Abstract

Phosphorus (P) nutrition is always a key issue regarding plants responses to elevated CO₂. Yet it is unclear of how elevated CO₂ affects P uptake under different nitrogen (N) forms. This study investigated the influence of elevated CO₂ (800 µl l⁻¹) on P uptake and utilization by Arabidopsis grown in pH-buffered phosphate (P)-deficient (0.5 µM) hydroponic culture supplying with 2 mM nitrate (NO₃⁻) or ammonium (NH₄⁺). After 7 d treatment, elevated CO₂ enhanced the biomass production of both NO₃⁻- and NH₄⁺-fed plants but decreased the P amount absorbed per weight of roots and the P concentration in the shoots of plants supplied with NH₄⁺. In comparison, elevated CO₂ increased the amount of P absorbed per weight of roots, as well as the P concentration in plants and alleviated P deficiency-induced symptoms of plants supplied with NO₃⁻. Elevated CO₂ also increased the root/shoot ratio, total root surface area, and acid phosphatase activity, and enhanced the expression of genes or transcriptional factors involving in P uptake, allocation and remobilization in P deficient plants. Furthermore, elevated CO₂ increased the nitric oxide (NO) level in roots of NO₃⁻-fed plants but decreased it in NH₄⁺-fed plants. NO scavenger 2-(4-carboxyphenyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide (cPTIO) inhibited plant P acquisition by roots under elevated CO₂. Considering all of these findings, this study concluded that a combination of elevated CO₂ and NO₃− nutrition can induce a set of plant adaptive strategies to improve P status from P-deficient soluble sources and that NO may be a signalling molecule that controls these processes.

Key words: ammonium, anthocyanin, atrnos1, elevated CO₂, nitrate, nitrate reductase, nitric oxide, nitric oxide synthase, nr, phosphorus acquisition, phosphate deficiency.

Introduction

Concentrations of atmospheric CO₂ have risen from about 270 µl l⁻¹ in pre-industrial times to over 380 µl l⁻¹ at present, and are predicted to reach between 530 and 970 µl l⁻¹ by the end of this century (IPCC, 2007). It has been demonstrated that increasing atmospheric CO₂ concentration has a profound impact on the growth and development of plants.
Many studies have investigated plant responses to elevated CO₂ on ecosystem, community, population, physiological, and molecular scales (Gibeaut et al., 2001; Teng et al., 2006; Jin et al., 2009; Niu et al., 2011a). However, relatively little information exists on the effects of elevated CO₂ on nutrition acquisition and metabolism. Previous studies have shown that elevated CO₂ generally stimulates the rates of carboxylation but suppresses the rate of oxygenation of ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) in C3 plants, thereby increasing plant growth and crop yield (Stitt et al., 1991; Drake et al., 1997). However, sustaining these increased rates requires increased nutrient uptake. Consequently, the role of nutrition availability is a key unresolved issue regarding plant responses to elevated CO₂.

Phosphorus is an essential element for plant growth and development. It plays important roles in energy transfer, signal transduction, photosynthesis, enzyme activation/inactivation, membrane synthesis and stability, and respiration, and is a structural component of nucleic acids and phospholipids (Abel et al., 2002; Vance et al., 2003; Chiou and Lin, 2011; Péret et al., 2011). However, the low solubility and high sorption capacity of phosphate in soils make it relatively unavailable to plant roots. In soil solution, concentrations of available P (mainly H₂PO₄⁻ and HPO₄²⁻) are generally less than 10 μM, which is well below the critical level needed for the optimal performance of crops (Schachtman et al., 1998; Batjes, 1997). The problem of P deficiency is mitigated by the application of concentrated fertilizers that provide soluble P to plants. This practice, however, is inherently inefficient due to chemical immobilization and surface runoff of P (Abel et al., 2002). Hence, low P availability is one of the major growth-limiting factors for plants in many natural and agricultural ecosystems (Barber et al., 1963; Raghothama, 1999).

When soil phosphorus availability is low, phosphorus uptake is increased by elevated CO₂; however, higher foliar phosphorus concentrations are also required to realize the maximum growth potential at elevated CO₂ (Conroy et al., 1997). Although the absolute increase in growth is greatest at high nutrient availability, relatively large gains in productivity can also be achieved at lower nutrient availability (Conroy et al., 1992). Notably, P deficiency reduces the assimilation of NO₃⁻ into the proteins, which might cause negative feedback on NO₃⁻ influx and/or stimulate NO₃⁻ efflux (Schjørring, 1986). Therefore, it seems that, under conditions of nutrition deficiency and elevated CO₂, plants sense changes in nutrition availability and trigger a set of plant adaptive responses to increase nutrition uptake and recycling. Numerous studies indicate that plants enhance P acquisition and mobilization to cope with low P availability by inducing a series of biochemical, physiological, and molecular adaptation strategies (Raghothama, 1999; Mukatira et al., 2001; Abel et al., 2002; Rubio et al., 2009; Ramaekers et al., 2010; Péret et al., 2011; Jin et al., 2012; Veneklaas et al., 2012). However, it is unclear how plants sense and respond to P deficiency under conditions of elevated CO₂.

Nitrogen (N) has been the centre of attention not only because it is the primary limiting nutrient in most temperate ecosystems, but also because the form of N supply can modify the response of plant growth to nutrition acquisition and elevated CO₂. It has been reported that N forms (NO₃⁻ versus NH₄⁺) can lead to contrasting responses of plant growth and metabolism to elevated CO₂. For example, elevated CO₂ increased NO₃⁻ uptake and nitrate reductase activity when tobacco was fed with NO₃⁻ but increased NH₄⁺ uptake and inhibited nitrate reductase activity with an NH₄⁺ supply (Matt et al., 2001). Likewise, under elevated CO₂, NH₄⁺-fed wheat showed greater increases in leaf area and smaller decreases in shoot protein concentration than NO₃⁻-fed plants (Bloom et al., 2002, 2010). Pharmacological experiments and studies of mutants with low activity of NIA (encoding nitrate reductase) showed that nitric oxide (NO) production was induced by NO₃⁻ and elevated CO₂ (Gojon et al., 1998), but was inhibited by ammonium, glutamine, or related downstream products of nitrate assimilation (Gojon et al., 1998). Recently, Carlisle et al. (2012) reported that both CO₂ concentration and N form strongly affected biomass production in hydroponically grown wheat, as well as nutrient concentrations in above- and below-ground tissues. Consequently, these differences between NO₃⁻ and NH₄⁺ nutrition led us to investigate how N form regulates the responses of P homeostasis of plants grown under elevated CO₂. Therefore, the aim of this study was to investigate the interactive effects of N form and elevated CO₂ on plant P uptake and utilization in a P-deficient medium. Arabidopsis was used as the test plant.

Materials and methods

Plant material and growth conditions

Seeds of Arabidopsis thaliana wild-type ecotype and mutants nr, AT1G77760 and AT1G37130 locus (Wang et al., 2004) and anos1, AT3G47450 locus (Guo et al., 2003), were surface-sterilized, and germinated on Petri plates containing 0.8% agar medium supplemented with one-fifth-strength nutrition solution (Niu et al., 2011a). After 7 d, seedlings of uniform size were transferred to 1.5 ml Eppendorf tubes whose bottoms were cut about 0.7 cm from the bottom to allow root growth into the nutrition solution. The tubes were inserted in holes of plastic boxes containing 200 ml of a half-strength nutrition solution, and plants were grown for 14 d. Then, each seedling was transferred to each pot containing 300 ml of nutrition solution. The composition (μM) of the nutrition solution was as follows: 1500 KNO₃, 500 MgSO₄, 1000 CaCl₂, 500 NaH₂PO₄, 250 (NH₄)₂SO₄, 10 H₂BO₃, 0.5 MnSO₄, 0.5 ZnSO₄, 0.1 CuSO₄, 0.1 (NH₄)₂MoO₄.10H₂O, and 25 Fe-EDTA (Haggaard and Arnon, 1938). The nutrition solution was renewed every 3 d and its pH was adjusted daily to 6.0 using 1 M NaOH. All plants were grown in controlled-environment growth chambers (Conviron E7/2, Winnipeg, Canada) with a humidity of 80%, a daily cycle of 22 °C/10 h day and 20 °C/14 h night. The daytime light intensity was 120 μmol photons m⁻² s⁻¹. At least eight independent replicates were used for each treatment.

After plants were further grown in pots for 14 d, treatments commenced. Plants were grown in chambers with a CO₂ concentration of either 350 ± 50 (ambient) or 800 ± 50 μl l⁻¹ (elevated CO₂). Meanwhile, N and P treatments were initiated. One set of plants was fully supplied with 2 mM NO₃⁻ as KNO₃, while the other was fully supplied with 2 mM NH₄⁺ in each CO₂ treatment. For the treatment of NH₄⁺ as the sole N source, 1 mM (NH₄)₂SO₄ and 1 mM K₂SO₄ were added. The low-P treatment had 0.5 μM NaH₂PO₄. The solution pH was buffered with 2 mM HEPES at pH 6.8 to minimize pH change, and was adjusted daily to 6.8 using 1 M NaOH. The treatment solutions were renewed every 2 d.
The NO-related treatments on wild-type plants were also initiated as follows: (i) ambient treatment: plants were grown continuously under ambient CO2; (ii) elevated CO2 treatment: plants were transferred to a chamber with a CO2 concentration of 800 ± 50 µl l−1; (iii) ambient + sodium nitroprusside (SNP) treatment: plants were transferred to the nutrition solution containing 100 µM SNP under ambient CO2; and (iv) elevated CO2 + 2-(4-carboxyphenyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide (cPTIO) treatment: plants were transferred to the nutrition solution containing 100 µM cPTIO under elevated CO2.

Analysis of total P in plant tissue
After 7 d treatment with ambient or elevated CO2, plants from various treatments were harvested, washed thoroughly with deionized water, divided into shoots and roots, and dried in an oven at 75 °C for 1 d. The samples were then weighed, digested in sulfuric acid/hydrogen peroxide, and analysed for total P concentration using the vanadium-molybdenum blue photometric method. The 'P absorbed per unit weight of roots' was calculated as the total amount of P per plant/root dry weight.

Anthocyanins
Total anthocyanins in leaves were extracted and determined as described by Hodges et al. (1999) with minor modifications. Approximately 0.1 g of fresh leaves was homogenized in 3 ml of methanol-1% HCl. Samples were centrifuged and 1 ml of the supernatant appropriately diluted in methanol-1% HCl was used for analysis. The difference in absorbance at 536 and 600 nm was used to calculate total anthocyanin content. Results were expressed as cyanidin-3-glucoside equivalents (mmol CO2+2-(4-carboxyphenyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide (cPTIO) treatment: plants were transferred to the nutrition solution containing 100 µM cPTIO under elevated CO2.

Chlorophyll concentration in leaves
After 7 d treatment, a portable chlorophyll meter (SPAD-502, Minolta, Japan) was used to measure chlorophyll content (Jin et al., 2009). Three leaves were selected randomly from each treatment and two SPAD readings were recorded for each leaf, avoiding the main veins during measurement.

Activity of acid phosphatases (APases)
The activity of APases in shoots and roots was determined according to the method of McLachlan et al. (1987) with minor modifications. After 7 d in low-P treatment, the seedlings were washed thoroughly with deionized water, divided into shoots and roots, and dried in an oven at 75 °C for 1 d. The samples were then weighed, digested in sulfuric acid/hydrogen peroxide, and analysed for total P concentration using the vanadium-molybdenum blue photometric method. The 'P absorbed per unit weight of roots' was calculated as the total amount of P per plant/root dry weight.

Quantitative PCR analysis
Total RNA was extracted using RNAiso Plus (Takara, Otsu, Shiga, Japan) from about 70 mg of fresh root tissues. At least five plants were used for extraction. All RNA samples were checked for DNA contamination before cDNA synthesis. cDNA was synthesized, and possible residual genomic DNA contamination was verified as described by us previously (Niu et al., 2011a). The mRNA levels of the genes PHOSPHATE STARVATION RESPONSE 1 (APHR1), PHOSPHATE TRANSPORTER 1 (APHT1), PHOSPHATE 1 (APPHO1), PHOSPHATE 2 (APPHO2), and PURPLE ACID PHOSPHATASE 2 (APpAP2) were detected using a SYBR Green RT-PCR kit (Takara) with the following pairs of gene-specific primers: APHR1, forward: 5'-ACAGCAATAACGCGGACGGGCAAG-3' and reverse: 5'-GCCAAGGTAGACGCAGGATA-3'; APHT1, forward: 5'-TACGCGAGAGAATAATGCG-3' and reverse: 5'-TTCCGGAGAACCAAATTGTC-3'; APPHO1, forward: 5'-ACCGAATCCGCAGAGGAA-3' and reverse: 5'-TTGAAGTACAGGCTTCGAGATA-3'; APAPP1, forward: 5'-CCTACCCACCCAGCGGAGACCGA-3' and reverse: 5'-TTCGCCGAGACCAAATTTGTC-3'; APPHO2, forward: 5'-ACGAGTACAGGCTTCGAGATA-3' and reverse: 5'-ACTCGGACATCTGGTACCAAACA-3'; APpAP2, forward: 5'-CATCAAGGTCTCTTGGAGACG-3' and reverse: 5'-TTGGACCGGGTGTGTAAGAGACG-3'.

Real-time PCR was carried out similar to as described by Niu et al. (2011a). A pair of primers for the housekeeping gene UBQ10 (forward: 5'-GGTGTGTAACCTTGGTCCAAGCA-3', reverse: 5'-CCCTCGTTA...
AACCAAGCTCAGTATC-3’) was used for a control reference gene for the PCR (Gan et al., 2006). Melting-curve analysis and gel electrophoresis of the PCR products were used to confirm the absence of non-specific amplification products. Relative expression levels were calculated by subtracting the threshold cycle (Ct) values for UBQ10 from those of the target gene (to give ΔCt) and then calculating 2−ΔCt, where Ct was the cycle number at which the fluorescence rose above the set threshold of the quantitative PCR.

Statistical analyses
All statistical analyses were conducted with DPS software (Stirling Technologies Inc., China). Means were compared using Student’s t-test or Fisher’s least significant difference test at P=0.05 in all cases.

Results

Plant growth and P uptake in low-P culture

After 7 d growth in ambient CO2 and P-deficient medium containing NO3− supplement as the sole N source, Arabidopsis leaves were dark green with a SPAD reading of 33. By comparison, the leaves of plants grown under the same nutrition conditions but with elevated CO2 were a normal green colour (Fig. 1a) with SPAD readings of 26 (see Supplementary Fig. S2a at JXB online). Elevated CO2 decreased the concentration of anthocyanins in leaves of NO3−-supplied plants (see Supplementary Fig. S3a at JXB online), indicating that elevated CO2 alleviated the P-deficiency-induced symptoms of the NO3−-supplied plants. However, with a supply of NH4+ as the sole N source, plants grown in the low-P solution had a similar appearance under both ambient and elevated CO2 treatments (Fig. 1a). Elevated CO2 did not change the concentrations of chlorophyll and anthocyanins (Supplementary Figs S2a and S3a). Furthermore, ammonium toxicity was not evident in the NH4+-fed plants.

Elevated CO2 enhanced shoot growth exclusively under NH4+ nutrition (Fig. 1b), whereas it enhanced root growth under NO3− nutrition (Fig. 1c). Elevated CO2 decreased the P concentration in shoots by 27% but did not alter it in the roots of NH4+-supplied plants. However, elevated CO2 increased the P concentration by 32 and 21%, respectively, in the shoots and roots of NO3−-fed plants (Fig. 1d, e). Meanwhile, elevated CO2 increased the amount of P absorbed per unit weight of roots of NO3−-fed plants by 56% but decreased that of NH4+-fed plants by 33% (Fig. 1g), indicating that NO3− nutrition facilitates P uptake in roots.

After 7 d growth in P-adequate medium with either N source, the leaves were a normal green colour (data not shown). CO2 treatment did not affect the concentration of anthocyanins in leaves, but NH4+ supply significantly increased SPAD readings (Supplementary Figs S2b and S3b). Elevated CO2 increased biomass production (Supplementary Fig. S1a, b), but decreased the P concentration and the amount of P absorbed per weight of roots.

Fig. 1. Images (a), fresh biomass production of shoots (b) and roots (c), concentration of P in shoots (d) and roots (e), total P content (f), and amount of P absorbed per weight of roots (g) of 5-week-old wild-type Arabidopsis grown for 7 d in P-deficient nutrition solutions with NO3− or NH4+ exposed to ambient CO2 (350±50 µl l−1) or elevated CO2 (800±50 µl l−1). Data are means ±SD (n=5). Asterisks indicate that the mean values are significantly different between the ambient and elevated CO2 treatments (P<0.05). DW, dry weight.
with the decrease being greater in the \( \text{NO}_3^- \) than in the \( \text{NH}_4^+ \) treatment (Fig. S1c, d).

**Physiological and morphological responses to P deficiency**

Elevated CO\(_2\) greatly enhanced the number of lateral roots in the \( \text{NO}_3^- \)-supplied plants but restrained it in the \( \text{NH}_4^+ \)-supplied plants (Fig. 2a). The root/shoot ratio of \( \text{NO}_3^- \)-fed plants was greater and that of \( \text{NH}_4^+ \)-fed plants was lower under elevated compared with ambient CO\(_2\) (Fig. 2b). Furthermore, compared with ambient CO\(_2\), elevated CO\(_2\) increased the total root surface area and root/shoot ratio of the \( \text{NO}_3^- \)-supplied plants but not that of the \( \text{NH}_4^+ \)-supplied plants (Fig. 2b). Elevated CO\(_2\) did not affect the length or density of root hairs of plants grown in either N treatment (data not shown).

Another general response of plants to P starvation is the enhanced activity of APases. APase activity in both the shoots and roots of \( \text{NH}_4^+ \)-supplied plants was similar between the ambient and elevated CO\(_2\) treatments (Fig. 3a, b). However, elevated CO\(_2\) strongly increased APase activity in the shoots and roots of \( \text{NO}_3^- \)-fed plants (Fig. 3a, b).

**Expressions of genes involved in P uptake, translocation, and allocation in P-deficient plants**

Increased expression of genes involved in P uptake, transport, allocation, and remobilization is a significant adaptive response of plants to facilitate external P acquisition and internal P utilization under P-limited conditions (Rubio et al., 2001; Vance et al., 2003; Chiou and Lin, 2011). Elevated CO\(_2\) enhanced the expression of the P-uptake gene \( \text{AtPHR1} \) and the P-transport gene \( \text{AtPHT1} \); their expression in shoots were increased by 8-fold and 3.7-fold, respectively (Fig. 4a–d). By contrast, elevated CO\(_2\) did not change the expression of \( \text{AtPHR1} \) and \( \text{AtPHT1} \) in the roots of \( \text{NH}_4^+ \)-fed plants, and decreased their expression in the shoots (Fig. 4a–d).

In order to observe the allocation and retranslocation of internal P between shoots and roots, the expression of \( \text{AtPHO1} \) and \( \text{AtPHO2} \) was analysed. Elevated CO\(_2\) increased \( \text{AtPHO1} \) expression in the shoots and roots of \( \text{NO}_3^- \)-supplied plants by 2.6-fold and 32%, respectively. In comparison, elevated CO\(_2\) increased \( \text{AtPHO1} \) expression in the shoots by 4.7-fold but decreased it by 34% in the roots of \( \text{NH}_4^+ \)-fed plants (Fig. 4e, f). Elevated CO\(_2\) increased the expression of \( \text{AtPHO2} \) by 8.8-fold in the shoots but decreased it by 76% in the roots of

Data are means ±SD (n=8) of two independent experiments. Asterisks indicate that the mean values are significantly different between the ambient and elevated CO\(_2\) treatments (\( P <0.05 \)).
Fig. 3. APase activity in shoots (a) and roots (b) of 5-week-old wild-type Arabidopsis grown for 7 d in P-deficient nutrition solutions containing NO$_3^-$ or NH$_4^+$ exposed to ambient CO$_2$ (350±50 µl l$^{-1}$) or elevated CO$_2$ (800±50 µl l$^{-1}$). Data are means ±SD (n=5). Asterisks indicate that the mean values are significantly different between the ambient and elevated CO$_2$ treatments (P <0.05). FW, fresh weight.

Fig. 4. Relative expression levels of the genes AtPHR1, AtPHT1, AtPHO1, AtPHO2, and AtPAP2 in the shoots and roots of 5-week-old wild-type Arabidopsis grown for 7 d in P-deficient nutrition solutions with NO$_3^-$ or NH$_4^+$ exposed to ambient CO$_2$ (350±50 µl l$^{-1}$) or elevated CO$_2$ (800±50 µl l$^{-1}$). Relative expression levels were calculated and normalized with respect to expression of UBQ10 mRNA. Data are means ±SD (n=5). Asterisks indicate that the mean values are significantly different between the ambient and elevated CO$_2$ treatments (P <0.05).
NO$_3^-$-supplied plants, whereas it did not significantly change its expression in the shoots of NH$_4^+$-fed plants (Fig. 4g, h).

**Possible role of NO in P nutrition under P deficiency and elevated CO$_2$**

NO was demonstrated recently to be a signal molecule involved in the regulation of root growth during P deficiency (Wang et al., 2010). We observed that elevated CO$_2$ resulted in stronger fluorescence intensity in the root tip and root-hair region in NO$_3^-$-fed plants but decreased it in NH$_4^+$-fed plants, compared with results under ambient CO$_2$ (Fig. 5a). To confirm the observation, the fluorescence of 15 roots from each treatment was measured. As shown in Fig. 5b, elevated CO$_2$ significantly increased the NO level in the roots of NO$_3^-$-supplied plants but decreased it in NH$_4^+$-supplied plants. A correlation was found between endogenous NO level and P concentration in the roots. Whereas the application of SNP (a NO donor) to the plants under ambient CO$_2$ tended to promote the P concentration to levels below those measured under elevated CO$_2$ (Fig. 6a), the addition of the NO scavenger cPTIO under elevated CO$_2$ reduced the amount of P absorbed per unit weight of roots in both NO$_3^-$- and NH$_4^+$-supplied plants and inhibited it to levels significantly below those measured under ambient CO$_2$ (Fig. 6c), suggesting some involvement of NO in modulating P uptake in roots. The treatment effect of total P uptake followed the same pattern (data not shown). These results implied that an appropriate concentration of endogenous NO in roots is critical for the regulation of elevated CO$_2$-induced P uptake in both NO$_3^-$ and NH$_4^+$ medium.

To confirm the above findings further, the effects of elevated CO$_2$ on the activity of NR and NOS were studied (Fig. 7). In the NO$_3^-$ treatment, elevated CO$_2$ increased NR activity in the shoots but decreased it in the roots (Fig. 7a, b). Elevated CO$_2$ also increased NOS activity in both the shoots and roots of the NO$_3^-$-fed plants (Fig. 7c, d). In the NH$_4^+$ treatment, elevated CO$_2$ did not affect the NOS and NR activity in shoots but inhibited their activity in roots (Fig. 7).

To further verify the role of NO in mediating elevated CO$_2$-induced uptake of P during P deficiency, mutants *nr* (an NR-reduced mutant) and *atnos1* (an NOS-reduced mutant) were used to observe their capacity of P uptake compared with wild-type *Arabidopsis*. Overall, the P concentrations of mutants *nr* and *atnos1* grown in both NO$_3^-$- and NH$_4^+$-supplied media were similar under ambient and elevated CO$_2$ (Fig. 8a, b). Specially, elevated CO$_2$ increased the P concentration in shoots of the *nr* mutant supplied with NO$_3^-$*. These results demonstrated that NO is the signal involved in the regulation of elevated CO$_2$-induced uptake of P during P deficiency.

**Discussion**

Previous studies have indicated that CO$_2$-dependent stimulation of growth is likely to enhance the requirements of plants for macronutrients such as N and P (Baxter et al., 1994; Kogawara et al., 2006; Lagomarsino et al., 2008). This study demonstrated that a combination of elevated CO$_2$ and nitrate induced a set of morphological, physiological, and molecular responses that enabled the plants to better access and utilize P and to alleviate P-deficiency symptoms.

Elevated CO2 improves P nutrition under a nitrate supply

The promotion of plant growth under elevated CO2 would be associated with increased requirements for mineral nutrition to optimize the nutrition balance in plants. This was the case in a 6-year Free Air CO2 Enrichment (FACE) experiment in which photosynthetic stimulation by elevated CO2 was largely regulated by N and P availability in the soil. (Lagomarsino...
Effect of elevated CO2 on P nutrition under different N forms | 363

In the present study, elevated CO2 enhanced biomass production in both NO3- and NH4+-fed Arabidopsis plants during P deficiency (Fig. 1). However, elevated CO2 preferentially stimulated specific P (pool) concentration as well as total P concentration and reduced the accumulation of anthocyanins in NO3−-fed plants. This result is consistent with the findings of Carlisle et al. (2012) that NH4+-supplied plants tended to have decreased nutrient concentrations with increasing CO2 concentration, while NO3−-supplied plants varied widely across CO2 treatments. The present study concluded that NO3− nutrition facilitates the P uptake of roots under elevated CO2.

To test whether the improved P uptake occurred only in NO3−-fed P-deficient plants under elevated CO2 conditions, we further examined the influence of elevated CO2 on P nutrition of P-adequate Arabidopsis supplied with different N forms. Interestingly, elevated CO2 only increased the shoot biomass, but decreased specific P uptake with the decrease being greater in the NO3− than the NH4+ treatment (Fig. S1). Numerous studies have elucidated that plants adapt to P deficiency through modifications of root architecture, carbon metabolism and membrane structure; exudation of carboxylates, protons and enzymes; and enhanced expressions of genes (Raghothama, 1999; Vance et al., 2003; Shenoy and Kalagudi, 2005; Shulaev et al., 2008; Wang et al., 2010). Therefore, the increase in P concentration in NO3−-fed Arabidopsis plants by elevated CO2 cannot be attributed to increased photosynthesis alone but also to the improved P nutrition of the plants through morphological, physiological, and molecular responses to P deficiency.

This study showed that NO3−-fed plants had more lateral roots but a shorter taproot under elevated compared with ambient CO2, whereas NH4+-fed plants had longer roots with fewer lateral roots under elevated CO2 (Fig. 2). In the field, particularly with no-till systems, P concentration is great in topsoil and declines substantially with depth (Lynch and Brown, 2001; Ao et al., 2010). The reduced primary root and increased lateral roots, resulting in a shallower root system, is a positive adaptive response to low-P availability by reducing inter-root competition within the same plant (Miller et al., 2003; Lynch, 2007). In addition, the greater root/shoot ratios seen in NO3−- compared with NH4+− supplied plants during P deficiency under high CO2 concentrations (Fig. 2) also favour P acquisition. Nevertheless, favourable root architecture may only play a minor role in increasing P uptake of plants under the combined conditions of P limitation and elevated CO2 in the hydroponic culture supplied with H2PO4−.

Figure 8. P concentration in shoots (a, c) and roots (b, d) of Arabidopsis NR-reduced mutant nr and nitric oxide synthase-reduced mutant atnos1 treated with P-deficient nutrition solutions containing NO3− or NH4+ exposed to ambient CO2 (350±50 µl l−1) or elevated CO2 (800±50 µl l−1) for 7 d. Data are means ±SD (n=5). Asterisks indicate that the mean values are significantly different between the ambient and elevated CO2 treatments (P <0.05).
Another general response of plants to P starvation is the enhanced activity of APases (Richardson et al., 2009; Tran et al., 2010). In bean plants, a high activity of APases contributes to the increased P-utilization efficiency through remobilization of P from old leaves to young tissues (Kouas et al., 2009). Similarly, the physiological function of root APases has also been demonstrated by Xiao et al. (2006) and Wang et al. (2009) where transgenic plants overexpressing APase genes exhibited greater P acquisition from an organic P resource than wild-type plants. Our results showed that elevated CO₂ increased APase activity in both the shoots and roots of Arabidopsis plants supplied with NO₃⁻, which is consistent with results reported in the literature (Lagomarsino et al., 2008). The enhanced APase activity, especially in the root of NO₃⁻-fed plants, under elevated CO₂ conditions (Fig. 3) would be expected to facilitate hydrolysis of organic P and thus plant P uptake in the field.

Biochemical and molecular studies have identified a number of genes that are involved in plant alteration in response to P starvation. PHR1 is a key transcriptional activator in controlling P uptake, allocation, and anthocyanin accumulation (Rubio et al., 2001; Nilsson et al., 2007). The enhanced expression of AtPHR1 under elevated CO₂ could activate numerous P-deficiency-response genes, which in turn change molecular, cellular, and physiological processes to cope with P deficiency. P assimilation is initiated by the transport of P into the roots and the number of P transporters present in the roots reflects the complexity and significance of the process. In Arabidopsis, the reduced P uptake activity is caused by a defect in targeting the PHT1 transporter to the plasma membrane (González et al., 2005; Jain et al., 2007). Our present study showed that elevated CO₂ enhanced the expression of AtPHT1 genes in the shoots and roots of NO₃⁻-fed plants with expression being much greater in the roots (Fig. 4), indicating that P transport was stimulated by elevated CO₂ in the NO₃⁻ medium.

Partitioning and allocation of internal P is also crucial for maintenance of P homeostasis within plants. AtPHO1 was first identified in Arabidopsis as a gene playing an important role in P transport from the roots to the shoots (Poirier et al., 1991), while AtPHO2 is responsible for P translocation from the shoots to the roots. It was reported that a pho1 mutant plant accumulated adequate P in the roots but less P in the shoots (Poirier et al., 1991; Hamburger et al., 2002; Stefanovic et al., 2007). The downregulated expression of AtPHO1 in the roots and the similar expression of AtPHO2 in the shoots of NH₄⁺-supplied plants in the present study (Fig. 4) probably form a negative-feedback loop against internal P recycling between shoots and roots. In contrast, the PHO2 gene, which regulates P uptake, allocation, and remobilization, is a target gene of miR399a pho2, which displays P toxicity with excessive P accumulation in the shoots of Arabidopsis (Aung et al., 2006). Accordingly, the high expression of AtPHO1 in the roots and AtPHO2 in the shoots of the NO₃⁻-supplied plants under elevated CO₂ (Fig. 4) indicated that internal P recycling between shoots and roots was stimulated by elevated CO₂ during the onset of P starvation. Furthermore, the enhanced AtPAP2 expression in shoots under elevated CO₂ (Fig. 4) indicated that elevated CO₂ could excite intracellular P remobilization during P deficiency.

A possible role of NO

It has been shown that P deficiency significantly increases the endogenous NO concentration in roots of white lupin (Wang et al., 2010). In this study, we observed that elevated CO₂ increased the NO level in roots of NO₃⁻-supplied plants, while the NO scavenger cPTIO inhibited specific P uptake by the root. In contrast, the NH₄⁺ supply was associated with a rapid decrease in NO production under elevated CO₂, while the NO scavenger cPTIO inhibited specific P uptake (Figs 5 and 6). These results are supported by recent observations that NO₃⁻ but not NH₄⁺ increased the NO level in the roots of tomato (Solanum lycopersicum) in both cadmium-free and cadmium-supplemented growth solutions (Luo et al., 2012). These results suggest that NO is partly responsible for NO₃⁻-facilitated P accumulation in plants.

It is unclear how elevated CO₂ changes the NO levels in roots under P deficiency. It is recognized that NR and NOS are two potential enzymatic sources of NO in plants (Neill et al., 2008). Although NOS genes have not yet been identified in plants (Neill et al., 2008), several studies support the presence of NOS activity in plants (Corpas et al., 2006; Valderrama et al., 2007). As shown in Fig. 7, NR activity in the shoots of NO₃⁻-fed plants was greater under elevated compared with ambient CO₂, while NR activity in the roots was lower under elevated CO₂ irrespective of N form. These results are in accordance with the findings of other studies (Buchanan et al., 2000; Poornachit and Darnell, 2004). Nitrate supply has been shown to enhance NR activity (Shaner and Boyer, 1976), whereas NH₄⁺ is an inhibitor of NR (Jin et al., 2011). On the one hand, increasing NO₃⁻ availability should enhance the NR-dependent NO production. Accordingly, a higher NO level in the roots of the NO₃⁻-fed plants and a lower NO level in the roots of NH₄⁺-fed plants under elevated CO₂ is partly due to the change in NR activity. On the other hand, elevated CO₂ enhanced the root uptake capacity for NO₃⁻, but not for NH₄⁺, in field-grown loblolly pine saplings (Bassirirad et al., 1996). Therefore, it is reasonable to propose that stimulated NO₃⁻ uptake under elevated CO₂ may facilitate NO production in roots, form a positive feedback loop, and upregulate P uptake.

Elevated CO₂ also increased the NOS activity of Arabidopsis plants supplied with NO₃⁻ but decreased it in NH₄⁺-fed plants (Fig. 7). It is well established that elevated CO₂ represses NIA in NH₄⁺-fed plants and increases NH₄⁺ uptake and assimilation, and the synthesis of glutamine (Gojon et al., 1998; Stitt and Krapp, 1999). Thus, increased NH₄⁺ uptake and assimilation under elevated CO₂ may restrain the activity of NR, and possibly of NOS. Furthermore, in mutants with low NIA activity, NO production was suppressed by NH₄⁺ (Gojon et al., 1998; Stitt and Krapp, 1999), which supports our findings.

In Arabidopsis, two mutants defective in NO production displayed altered phenotypes. The nr mutant had a deletion...
of the major NR gene, NIA2, and an insertion in the NIA1 NR gene (Wang et al., 2004), and the atrinos1 mutant has a mutation in an NOS structural gene NOSI (Guo et al., 2003). In this study, the P concentrations of both mutants, nr and nos, were similar under elevated and ambient CO2 (Fig. 8), suggesting that regulation of P nutrition under elevated CO2 is NO-signalling dependent. However, relative to the ambient CO2 condition, elevated CO2 tended to increase the P concentration in both the shoots and roots of NO3−-fed plants. These results are consistent with a major or general role of NO in the regulation of plant development and metabolism. The results also support our hypothesis that elevated CO2 increases P uptake in NO3−-fed plants but suppresses it in NH4+.-fed plants through the effect on the activity of NR and/or NOS, leading to changes in NO production and physiology. However, the details about how NO exerts its effects on P nutrition remain unclear. The studies by Neill et al. (2003) and Niu et al. (2011b) on interrelations between NO, Ca2+, cyclic ADP ribose, cyclic GMP, salicylic acid, reactive oxygen species, hydrogen peroxide signalling, and protein kinases have provided an important focal point for future research.

Overall, although previous reports have provided other evidence concerning NH4+ nutrition facilitating P uptake in the roots of different plant species. Here, using wild-type Arabidopsis plants, we demonstrated that NO3− nutrition facilitates the P uptake in roots from P-deficient soluble sources under elevated CO2 by upregulating plant adaptive strategies. The increase in NO production may be a signalling pathway controlling the above process. To our knowledge, this finding uncovers a mechanism that has not been described previously and provides a new insight into N forms regulating P nutrition under elevated CO2, an important part of climate change in the 21st century. This study also helps to determine whether the carbon costs of P efficiency under elevated CO2 should be prioritized in crop improvement programmes.

Supplementary data

Supplementary data are available at JXB online.

Supplementary Fig. S1. Effect of elevated CO2 and N form on shoot and root fresh biomass production, P concentration in whole plants, and amount of P absorbed per weight of roots.

Supplementary Fig. S2. Effect of elevated CO2 and N form on chlorophyll content (SPAD readings) of wild-type Arabidopsis grown in P-deficient (0.5 µM) (a) and P-adequate (0.5 mM) (b) nutrition solutions containing NO3− or NH4+.

Supplementary Fig. S3. Effect of elevated CO2 and N form on anthocyanin content of wild-type Arabidopsis grown in P-deficient (0.5 µM) (a) and P-adequate (0.5 mM) (b) nutrition solutions containing NO3− or NH4+.
