From 10th Symposium on Lactic Acid Bacterium
Egmond aan Zee, the Netherlands. 28 August - 1 September 2011

**Abstract**

Sourdough has played a significant role in human nutrition and culture for thousands of years and is still of eminent importance for human diet and the bakery industry. *Lactobacillus sanfranciscensis* is the predominant key bacterium in traditionally fermented sourdoughs.

The genome of *L. sanfranciscensis* TMW 1.1304 isolated from an industrial sourdough fermentation was sequenced with a combined Sanger/454-pyrosequencing approach followed by gap closing by walking on fosmids. The sequencing data revealed a circular chromosomal sequence of 1,298,316 bp and two additional plasmids, pLS1 and pLS2, with sizes of 58,739 bp and 18,715 bp, which are predicted to encode 1,437, 63 and 19 orfs, respectively. The overall GC content of the chromosome is 34.71%. Several specific features appear to contribute to the ability of *L. sanfranciscensis* to outcompete other bacteria in the fermentation. *L. sanfranciscensis* contains the smallest genome within the lactobacilli and the highest density of ribosomal RNA operons per Mbp genome among all known genomes of free-living bacteria, which is important for the rapid growth characteristics of the organism. A high frequency of gene inactivation and elimination indicates a process of reductive evolution. The biosynthetic capacity for amino acids scarcely available in cereals and exopolysaccharides reveal the molecular basis for an autochtonous sourdough organism with potential for further exploitation in functional foods. The presence of two CRISPR/cas loci versus a high number of transposable elements suggests recalcitrance to gene intrusion and high intrinsic genome plasticity.

**Background**

The use of sourdough is documented for > 5,000 years and of eminent industrial importance in the production of baked goods amounting to more than 3 million tons of baked goods annually [1]. Annual per capita consumption of baked goods in Europe is 50-85 kg with up to 20% involving sourdough fermentations with wheat or rye, i.e. a total of > 3 million tons. To date, no bacterial genomes from strains adapted to this huge man made habitat in millions of generations are available. *Lactobacillus sanfranciscensis* was first described in 1971 by Kline and Sugihara who isolated and characterized obligately heterofermentative lactobacilli from San Francisco sourdoughs [2]. The name *Lactobacillus sanfrancisco* refers to the city where the sourdoughs from which the organism was isolated had been propagated for more than 100 years. At that time the species was not included in the Approved Lists of Bacterial Names and had no standing in bacteriological nomenclature until the name was revived by Weiss and Schillinger in 1984 [3]. To follow the Rules of the International Code of Nomenclature of Prokaryotes the species epithet was changed to *L. sanfranciscensis* [4]. Sourdough fermentations worldwide are characterized by a highly stable association of yeasts and lactic acid bacteria. In rye and wheat sourdoughs with a tradition of continuous propagation by back-slopping procedures, *L. sanfranciscensis* is the probably the most adapted species and regarded as
autochthonous key organism of the sourdough microbiota [5,6]. Its phylogenetic position within the genus lactobacillus is shown in Figure 1. Multiple metabolic activities of *L. sanfranciscensis* have been described in the literature that contribute to the quality of sourdough and baked goods. With the exception of one report by Groeneveld *et al.* [7], who allotted isolates from fruit flies exhibiting 97% rDNA sequence homologies as *L. sanfranciscensis*, this species has only been isolated from sourdough, while strains of all other species found in sourdough are frequently isolated also from other habitats. None of the genome-sequenced strains of these genera, e.g. *L. plantarum* or *L. reuteri* were isolated from sourdough. This raises the question for the role of man in evolution of *L. sanfranciscensis*.

The sourdough microbiota including *L. sanfranciscensis* contribute to dough rheology and flavour properties due to a strong acidification by an optimized carbohydrate metabolism and the liberation of precursors of volatile compounds by the proteolytic system [8-10] and the catabolism of specific amino acids [5,10,11]. Formation of exopolysaccharides (homopolysaccharides and fructooligosaccharides) enhance texture, shelf life and nutritional value [12]. The sequenced strain *L. sanfranciscensis* TMW 1.1304 was isolated in 2006 from a commercial mother sponge with a tradition of continuous propagation. The presence of this strain in this sourdough starter was demonstrated over a period of at least 20 years, and it accounts for more than 90% of the microflora of that product.

**Results and discussion**

**General genomic features**

The *L. sanfranciscensis* TMW 1.1304 genome project allowed the assembly of a circular chromosomal sequence...
of 1,298,316 bp and two additional plasmids of 58,739 bp and 18,715 bp. The genome size of strain TMW 1.1304 was estimated at approximately 1.3 Mbp on the basis of results obtained by pulsed-field gel electrophoresis of chromosomal DNA restriction fragments. A previous estimation of the apparent genome size based on four strains of \textit{L. sanfranciscensis} isolated from Italian sourdoughs and the type strain DSM 20451\(^\text{T}\) indicates 1.4 Mbp [13]. Thus, the \textit{L. sanfranciscensis} genome is the smallest genome within the genus \textit{Lactobacillus} so far followed by the recently published genome of \textit{Lactobacillus iners} AB-1 with 1,304 Mbp [14].

The general features of the genome are presented in Table 1. The average orf length is 835 and the codon density is 87.1, which is in the range of other lactobacilli (Additional file 1).

On the basis of analysis of the GC skew (G-C/G+C), the cumulative GC-skew and the location of characteristic genes (chromosomal replication initiator protein \textit{DnaA}), we could identify a typical bacterial origin of replication and its beginning was assigned as base-pair one of the genome. Thus, two equal replication arms (replichores) were present and the locations of the predicted 1,437 coding sequences on the two strands correlated well with the direction of replication (Fig. 2). There were 153 pseudogenes found randomly distributed in the chromosome. Genes encoding replication functions overlap sequences with significant changes in GC skew indicating the location of the origin of replication (oriC). This region harbors the genes for the replication initiator protein (\textit{dnaA}), the beta subunit of DNA polymerase III (\textit{dnaN}), and the DNA gyrase subunits A and B (\textit{gyrA} and \textit{gyrB}).

The arrangement of these genes, \textit{dnaA-dnaN-recF-gyrB-gyrA}, is similar to that found in other Gram-positive bacterial genomes studied so far. Five \textit{DnaA}-box consensus sequences (TTATNCACA) were found upstream of \textit{dnaA} and three in the \textit{dnaA-dnaN} intergenic region. Opposite of the genome between position 628,700 and 628,800 a second change in GC skew indicates the replication terminus.

### Stable RNA gene density and codon usage bias

Seven rRNA operons and 61 tRNA genes were detected, demonstrating an intriguingly high density of genes for stable RNAs in the genome of \textit{L. sanfranciscensis} TMW 1.1304. Analysis of approx. 1000 complete genomes (Additional file 2) available in GenBank revealed that \textit{L. sanfranciscensis} TMW 1.1304 has the highest rRNA operon density (5.39 per Mbp) among all known free-living organisms. The only genome with a higher rRNA gene density is that of \textit{Candidatus Carsonella ruddii} PV (1 rRNA operon in its 0,159662 Mbp genome), an obligate insect endosymbiont not capable of autonomous growth whose status as a living organism is debatable [15] due to the lack of most replication, transcription and translation genes considered as essential for living cells. Interestingly, 50% of the top 20 species with the highest rRNA gene densities (rRNA gene densities above 2.9 per Mbp; species represented by more than one sequenced genome were only counted once; genomes from non-free-living bacteria with candidatus status were disregarded) were lactic acid bacteria, i. e. various \textit{Lactobacillus} and \textit{Streptococcus} species (Additional file 3).

Table 1 General features of the \textit{L. sanfranciscensis} genome compared with genomes of other species, which are found in sourdough (however, the strains whose genomes have been sequenced were isolated from other sources). Data are from this study and [59]

* values in brackets are for the plasmids pLS1 and pLS2, respectively.
rapidly initiating fermentative metabolism and fast
growth which in combination with their specifically
adapted metabolism (see below) could help to out-compete other contaminating bacteria. This strategy may also
hold true for other lactic acid bacteria with a high rRNA
operon density such as *Lactobacillus delbrueckii* subsp.
*bulgaricus* (second-ranking after *L. sanfranciscensis*
with an rRNA operon density of 4.85/Mbp of strain ATCC
BAA-365) which is one of the classical starter organisms
responsible for rapid lactic fermentation during yoghurt
production.

Numerous microbial genomes reveal a codon usage
bias (CUB), i.e. a pronounced preference for a specific
set of codons (named major codons), in genes whose
products are required in large quantities, which
improves translation efficiency of these genes and con-
tributes to optimizing cell growth [18,19][20]. The
*L. sanfranciscensis* genome revealed a relatively strong
CUB. A closer look at the set of genes that are transla-
tionally optimized in this organism revealed that the top
80 hits expectedly contained many genes (44) encoding
ribosomal proteins and translation factors (Additional

**Figure 2** Genomic atlas of *L. sanfranciscensis* TMW 1.1304. From the outer circle inward, CDS on the forward strand (red), CDS on the reverse strand (blue), Pseudogenes on both strands (black), tRNA genes (green), GC content deviations from the average GC-content (green, low GC spike and orange, high GC spike), GC skew (grey). The GC% and GC skew (C-G)/(C+G) were calculated in a window of 10000 nt, in steps of 200 nt.
file 4), but also with the exception of the ribulose-5-
phosphate epimerase gene all genes for the formation of
lactate, CO₂ and ethanol via the phosphoketolase path-
way, underscoring the importance of the efficient
expression of this pathway for L. sanfranciscensis.

Carbohydrate metabolism
Consistent with the classification of L. sanfranciscensis as a
heterofermentative lactic acid bacterium (LAB) all genes
required for the phosphoketolase pathway are present in
the L. sanfranciscensis genome whereas no homologues to
transaldolase or transketolase were found. In silico ana-
alyses revealed that the sequenced L. sanfranciscensis strain
is likely to use maltose, fructose, ribose and gluconate as
carbon sources (Additional file 5). Additionally, two copies
of a transporter for arabinose were found (LSA_1450,
LSA_1460; LSA_1460) which only one seems to be functional as
L. sanfranciscensis was found to be truncated at the 3’
end. The presence of two genes for oligo-1,6-glucosidase
(LSA_05810; LSA_01770) indicates the ability to hydrolyse α-1,6-D-glucosidic
linkages in oligosaccharides produced from starch and glyco-
gen (isomaltulose, isomaltotriose, panose and isomaltose).
Except for maltose phosphorylase (LSA_01510) and a
truncated alpha-glucosidase (LSA_05800) no additional
ORFs for glycoside hydrolases were annotated.

Growth of L. sanfranciscensis with maltose as carbon
source is generally accelerated when fructose, citrate or α-
ketoglutarate are used as alternative electron acceptors.
[21,22]. Several uptake systems for possible electron accep-
tors were present. Fructose can be transported by a fruc-
tose permease (LSA_2810) and reduced to mannitol using
a mannitol-2-dehydrogenase (LSA_02820). Two genes for
citrate-sodium symporters (LSA_08630 and LSA_13030)
and one gene encoding a malate uniporter protein
(LSA_02110) suggest uptake of citrate and malate. Genes
necessary to reduce citrate to lactate are also present
(LSA_12980 and LSA_12990 for citrate lyase, LSA_13020
for oxaloacetate decarboxylase, while no homologue gene
for a succinate dehydrogenase which is necessary for the
utilization of malate as electron acceptor was found.

The use of α-KG as electron acceptor by conversion to
2-hydroxyglutarate by LAB was previously mentioned by
Radler and Broehl, 1984[23]. Recently, reduction of α-keto-
gluturate to 2-hydroxyglutarate was demonstrated in L.
sanfranciscensis indicating that α-ketoglutarate was used
preferably as electron acceptor and NADH-dependent
hydroxyglutarate dehydrogenase activity was confirmed by
enzymatic analysis of crude cell extracts of L. sanfrancis-
censis[22]. Several ORFs with putative α–hydroxy acid dehy-
drogenase activity were present.

As expected, the genome of L. sanfranciscensis only
encodes an incomplete citrate cycle as only genes for
fumarate hydratase (LSA_12040), malate dehydrogenase
(LSA_02100; LSA_04670) and citrate lyase (LSA_12980
and LSA_12990) are present.

Pyruvate metabolism
Due to a frameshift in the pyruvate oxidase gene (EC
1.2.3.3/ LSA_00220) direct conversion of pyruvate to
acetyl phosphate is not possible for L. sanfranciscensis.
Therefore, the organism most likely converts pyruvate
to acetate via lactate first and then generates acetyl
phosphate from acetate. Enzymes required for redund-
ant pathways like formate C-acetyltransferase (EC
2.3.1.54) or acetaldehyde dehydrogenase (EC 1.2.1.10)
were not encoded by the L. sanfranciscensis genome but
in lactobacilli with larger genomes like L. plantarum or
L. casei. In spite of the presence of only a relative low
number of pyruvate dissipation enzymes in the L. san-
franciscensis genome, a high degree of redundancy for
lactate dehydrogenase (ldh) encoding genes was
observed as at least three L-lactate dehydrogenases
(LSA_09870, LSA_11450, LSA_13040) and three D-lac-
tate dehydrogenases (LSA_00860, LSA_10990,
LSA_12510) were found, among which LSA_11450 and
LSA_12510 are pseudogenes. The presence of several
copies of ldh genes in other lactobacilli, e.g. L. plan-
tarum[24] or L. casei ATCC 334 [25] in connection
with the broad range of substrate selectivity described
for those enzymes stresses their key function of NAD+
regeneration. Pyruvate can be produced by L. sanfrancis-
censis from a number of substrates. Besides the usual
formation from sugars and gluconate via the phosphoke-
tolase pathway, pyruvate can be generated from aspara-
gine and alanine via transamination and from malate
catalysed by malate dehydrogenase (LSA_02100, EC
1.1.1.38).

Formation of exopolysaccharides (EPS)
Formation of EPS is a trait often found in lactic acid
bacteria [26]. Heterofermentative lactobacilli occurring
in sourdough mostly synthesize glucan or fructan homo-
polymers. These are formed from sucrose by secreted or
cell-anchored glucosyltransferases, which convert the
succrose into high-molecular-weight polymers, with the
concomitant release of the respective hexose.

In TMW 1.1304 two genes encode respective glucosy-
transferases, both carrying a LPXTG sortase recognition
motif. A plasmid encoded dextransucrase (LSA_2p00510)
with a best protein match (85%) to a dextransucrase of
L. reuteri JCM 1112 is obviously not active due to the lack of
ca. 500 aa residues at the N-terminus and an atypical
small molecular weight. A levansucrase (LSA_LSA_02160)
was found to be identical to a levansucrase previously
described by Tieking et al. from L. sanfranciscensis TMW
1.392 [27]. Interestingly, a 48 aa residue deletion
corresponding to 4 direct repeats (PVNPSQPTTPAK) in the PXX motif of the C-terminal cell wall anchor is observed.

The production of EPS by TMW 1.1304 can be demonstrated by growing the strain on mMRS containing 80 g l⁻¹ sucrose. To analyze the type of the polymer, the EPS was precipitated by adding two volumes of ethanol (99%) and incubation at 4°C for 18 h. EPS was hydrolyzed with perchloric acid at 100°C for 3 h and sugar monomers were analyzed with HPLC as described by Waldherr et al, 2008 [28]. Under these conditions the EPS produced by TMW 1.1304 was demonstrated to consist of fructose, indicating that EPS is a high molecular fructan and the levansucrase is functional.

Besides their role for bacterial metabolism, for which protective functions and an altered metabolite profile as a result of alternative use of electron acceptors are discussed, exopolysaccharides impact on crumb structure as a result of alternative use of electron acceptors are discussed. Furthermore, EPS is a high molecular fructan and the levansucrase is functional.

Besides their role for bacterial metabolism, for which protective functions and an altered metabolite profile as a result of alternative use of electron acceptors are discussed, exopolysaccharides impact on crumb structure and shelf life of sourdough breads. Fructans and fructooligosaccharides likely produced by TMW 1.304 may serve further functional aspects in nutrition and medicine [29].

Amino acid metabolism

In silico analyses of the genome of L. sanfranciscensis TMW 1.1304 indicate the potential to synthesize de novo four amino acids (alanine from pyruvate, aspartate from oxaloacetate, glutamate and glutamine. L-alanine can be converted into L-cysteine using a cysteine desulfurase (EC 2.8.1.7, LSA_0990), while arginine, lysine and asparagine result from conversion pathways of L-aspartate. Therefore, L. sanfranciscensis is auxotroph for the remaining 12 amino acids (Table 2). As concentrations in wheat of aspartate, asparagine and glutamate are low, preservation of the biosynthetic pathways for these amino acids appears to be maintained as an adaptation to the sourdough environment.

Purine and pyrimidine biosynthesis

The enzyme required to generate 5-phosphoribosyl-1-pyrophosphate (PRPP) from the phosphoketolase pathway intermediate ribulose-5-phosphate (EC 5.3.1.6/LSA_04470 and EC 2.7.6.1/ LSA_04050; LSA_09930) are present in L. sanfranciscensis. As described for L. gasseri [30] six of the subsequent nine enzymes required to generate IMP from PRPP seem to be absent in L. sanfranciscensis. However, guanosine and adenosine as well as the corresponding nucleotides could be generated from IMP.

Although all genes necessary for the de novo synthesis of pyrimidines are present, L. sanfranciscensis is presumably auxotrophic for pyrimidines. The gene for dihydroorotase (EC 3.5.2.3; LSA_05890, LSA_05900), one of the five enzymes needed to generate UMP from carbamoyl-phosphate seems to be inactive due to a frameshift. Besides the dihydroorotase gene no additional pseudogenes are present in the pyrimidine metabolism of L. sanfranciscensis.

Cofactors

Similar to other lactobacilli, L. sanfranciscensis appears unable to synthesize most cofactors and vitamins like folate, thiamine, riboflavin, vitamin B6, nicotinate and nicotinamide. In silico analysis predicts that this organism can utilize both nicotinate and nicotinamide to generate NAD. However, this is only possible as two of the key enzymes, nicotinamidase (EC 3.5.1.19) and nicotinate phosphoribosyltransferase (EC 2.4.2.11) are encoded by the plasmid pLS2 (LSA_2p00220, LSA_2900230). Although only one gene involved in cobalamin synthesis (cobyrinic acid a, c-diamide synthase, EC 6.3.5.11; LSA_2900630) was encoded by the sequenced strain L. sanfranciscensis TMW1.1304, growth experiments showed that 8 of 11 L. sanfranciscensis strains tested were able to grow on vitamin B12 free media (Difco®) indicating that those strains were able to synthetize cobalamin de novo.

Proteolytic system

The predicted auxotrophy for 12 amino acids for L. sanfranciscensis was consistent with the presence of a large number of peptidases, proteases and transport systems for amino acids and peptides (Additional file 6). A complex proteolytic system ensures not only the supply with essential amino acids but also likely provides L. sanfranciscensis with a selective advantage in its protein-rich environment.

| L. johnsonii NC 533      | 25                          | 1.99              | 20                         | [61]               |
| L. casei ATCC 334        | 27                          | 3.08              | 3                          | [62]               |
| L. gasseri ATCC 33323    | 29                          | 1.89              | 17                         | [30]               |
as acquisition of amino acids from the environment is energetically more favourable than de novo synthesis [10]. The absence of an extracellular protease (prt) gene in the genome of *L. sanfranciscensis* reflects its high adaptation to and the associated dependency on sourdough. In contrast, dairy lactobacilli with comparable auxotrophy for amino acids like *L. helveticus* or *L. acidophilus* encode *prt* genes for proteinase production as milk only has low proteolytic activity and therefore degradation of casein to oligopeptides is a prerequisite for the growth of lactic acid bacteria in milk [31,32].

Peptides and amino acids present in the sourdough environment are internalized by peptide transporters and amino acid permeases. The *L. sanfranciscensis* genome encodes a di-/tripeptide transporter *dpT* (*LSA_04370*) and a complete oligopeptide transport system Opp. All five genes of the Opp system (*oppD, oppF, oppB, oppC, oppA*) are organized in an operon (*LSA_0280-LSA_0320*). In addition to several amino acid transporters with unknown specificity, ABC transporters for glutamine (*glnHMPQ, LSA_13380-13410*), methionine (*LSA_12550-12560, LSA_0940, LSA_08450*) and cystine (*tcyABC, LSA_01990, LSA_8550, LSA_8540, LSA_10490*) are predicted. Additionally a lysine-specific permease (*LSA_11550*), a serine-threonine antiporter (*steT, LSA_03230*), an arginine-ornithine antiporter (*arcD, LSA_12260*), a choline-glycine betaine transporter (*LSA_11780*) and a γ-aminobutyrate permease (*LSA_8760*) are present.

*L. sanfranciscensis* has 20 genes encoding cytoplasmatic peptidases of different specificity to hydrolyze incorporated peptides into free amino acids. (Additional file 6). Many of the genes were described in *L. sanfranciscensis* previously [33], but the genome sequence included novel genes with homology to the *pepB, pepD, pepE, pepM, pepO, pepQ*, and *pepV*. Compared to other LAB no correlation between amino acid auxotrophy and content of cytoplasmatic peptidases can be observed.

**Regulators**

Based on the presence of conserved functional domains 2 two-component regulatory systems and 38 transcriptional regulators including five pseudogenes were predicted (Additional files 7 and 8). Compared to *L. acidophilus* NCFM that harbours 9 two-component regulatory systems, this is a quite low number of genes involved in gene regulation and might reflect adaptation to a stable and nutrient-rich environment, where less adaptive regulation is required [34][30]. Like for other sequenced lactobacilli the numerically predominant regulatory protein families are repressors, i.e. e. MarR (five members), AcrR (four members) and MerR (four members). Besides *cspA* and the 2 two-component regulatory systems only two transcriptional activators both belonging to the LysR family were predicted. *L. sanfranciscensis* has three genes encoding for sigma factors. Besides the primary sigma-factor *rpoD* (*LSA_7720*) two genes for *rpoE* (*LSA_03460 and LSA_4550*), a sigma factor involved in high temperature and oxidative stress response are present.

**Phage defense/restriction/modification systems**

CRISPR loci play a critical role in the adaptation and persistence of a microbial host in a particular ecosystem. The observed similarity between spacers and phage or plasmid sequences has led to the hypothesis that CRISPRs may provide resistance against foreign DNA determinants [35-39]. Using CRISPRFinder [36], a web tool to identify clustered regularly interspaced short palindromic repeats (CRISPR) we identified two CRISPR loci. A chromosomally located CRISPR/cas system consists of three cas genes followed by two 29 bp CRISPR spacers. Repeat length (36 bp) and sequence similarity indicates its belonging to the Lsal1 family. A plasmid-located CRISPR/cas system consists of 5 cas genes and a CRISPR with 14 spacers, where the 28 bp repeats are separated from the cas genes by an IS607-family transposase gene. Repeat size (29bp) and sequence as well as spacer size (32/33bp) are identical to *L. brevis* ATCC 367 CRISPR Ldbu1-family [40]. Only one other plasmid-encoded CRISPR/cas system was identified on the *L. sanfranciscensis* genome and the chromosomal spacer 2 with 93 % similarity to *L. plantarum* plasmid pLTK2 (AB024514). No hit was found for a known phage sequence. While phage infections and spread in sourdough cultures may be hampered by the solid texture of the fermentative mass in batch systems the presence of CRISPR/cas may generally account for genetic stability of this strain in the sourdough environment making it a stable element over decades of fermentation.

**Mobile elements**

The presence of 111 transposases (including 25 pseudogenes) in IS elements in five different IS element families (IS3, IS30, ISL3, IS200/605, IS256) represent 7.7% of the ORFs found and are, as a result of the small chromosome, found in higher proportion than in other lactobacilli. Thus, an idea of facilitated niche adaptation of a distinct *Lactobacillus* subpopulation by a relative increase of genome plasticity is supported.
Stress response
Among genes related to heat, cold, acid, DNA damage and starvation genes related to the capability to respond to osmotic and oxidative stress are pronounced despite the small genome, suggesting that *L. sanfranciscensis* frequently faces such stresses. Generally, tolerance to oxygen of lactic acid bacteria requires the presence of catalase and/or NADH oxidases or several thiol-active enzyme systems including the thioredoxin-thioredoxin reductase couple, the glutathione-GshR system and a cyst(e)ine uptake and metabolism. On the basis of sequence similarity beside a NADH oxidase (LSA_05610) we identified in *L. sanfranciscensis*, a glutathione reductase (LSA_2p00270), a glutaredoxin-like protein (LSA_04700), two thioredoxin reductases (LSA_02530, LSA_05170), a putative thioredoxin peroxidase (LSA_09790), three thioredoxin-like proteins (LSA_08950, LSA_02610, LSA_06080) and a cyst(e)ine transport protein (LSA_08550). It was previously reported that a glutathione reductase negative mutant strain of *L. sanfranciscensis* DSM20451T lost oxygen tolerance and exhibited a strongly decreased aerobic growth rate compared to either the growth rate under anaerobic conditions or that of the wild-type strain. Moreover aerobic growth was restored by the addition of cysteine [45].

The production of inhibitory substances by sourdough LAB could provide another selective advantage for the producer strains [46]. Bacteriocins so far discovered from sourdough LAB and include the bacteriocins bavarian A [47], plantaricin ST31 [48] and the bacteriocin-like inhibitory substance *L. sanfranciscensis* C57. [49].

No functionally active bacteriocin genes are found in the genome. Only two truncated genes sharing 100% with *papA* encoding pediocin were found. Thus, bacteriocin production cannot be the reason for the long term competitiveness of this bacterium in sourdough.

Plasmids and plasmid encoded traits
Two plasmids pLS1 and pLS2 were present in strain TMW 1.1304. While plasmid-encoded traits for lactobacilli frequently include genes for sugar metabolism plasmids pLS1 and pLS2 harbour genes involved in nucleotide/NADH metabolism and are further characterized by the presence of many orfs encoding transposases.

The total DNA sequence of pLS1 consists of 58,739 bp with a GC content of 37.6 % encoding 59 orfs. Two genes encoding Rep B (replication associated replication protein) and RepA are homologous to the corresponding genes of the *L. brevis* plasmid pLB925A04 that is a theta type replication plasmid of the pAMB-1-family [50]. A truncated dextranucrase (LSA_2p00510) is discussed above. PLS1 contains a CRISPR/cas locus further supporting the importance of this function even at an enhanced copy number (see above).

The total DNA sequence of pLS2 consists of 18,715 bp with a GC content of 36.1 % and encodes 19 orfs. The replication protein RepB shows 80% similarity to a RepB protein of *Enterococcus faecium* E1636 (EMBL E13F23229.1) and 40 % to a RepB of plasmid pLTK13 (EMBL BAG67041), a rolling circle replicating plasmid of *L. plantarum* L137. Replication of the lagging strand of RC plasmids initiates from their single-strand origins (SSOs). SSOs have a high potential for intrastrand pairing and based on their secondary structures, several types of SSOs have been identified [51,52]. PLS2 contains a palindromic region (position 21–58) whose secondary structure is similar to the ssoA-type origin. A restriction / modification system consists of a cytosine-specific methyltransferase followed by a restriction endonuclease gene similar to the McrBC restriction endonuclease system of *Rhodobacter capsulatus* ATCC BAA-309 (EMBL ADE85042.1).

Material and methods
Strain selection, strain purification and DNA isolation
For sequencing a strain without any laboratory transfers was selected to ensure sequencing of a truly sourdough adapted clone. Therefore, the strain was isolated on mMRS [53] at 30°C from “Böcker Reinzuchtsauer”, a rye sourdough starter, which is now propagated for 100 years in the same tradition, and only propagated on laboratory media to obtain enough DNA for sequencing. Dilutions of a sourdough sample were spread directly on mMRS agar plates. Plates were incubated under anaerobic conditions at 30°C for 3–5 days. Genomic DNA was isolated with the EZNA DNA reagent set (Omega Bio-Tek) according the provided protocol for Gram positive bacteria.

Sequencing strategy
Sequencing was done in a combined Sanger/454-pyrosequencing approach. 454 sequencing resulted in 187,929 reads with an average read length of 250 nucleotides giving ~45 Mbp sequencing data corresponding to a 33-fold coverage. In addition 10,000 genomic fragments with typically 3kb to 5 kb inserts were cloned into the TOPO

http://www.microbialcellfactories.com/content/10/S1/S6
TA vector (Quiagen, Hilden) and sequenced on an ABI 3730 capillar sequencer from both ends. The ABI sequences resulted in 19.569 reads corresponding to an additional coverage of 13 fold. Remaining gaps were closed by sequences generated on gap-spanning PCR products by an ABI 3730 capillar sequencer. The overall quality was set to a minimum confidence of PHRED 45 for the complete genome.

This genome project has been deposited in the European Molecular Biology Laboratory (EMBL)/Gen- Bank under the accession numbers CP002461 (chromosome), CP002462 (pLS1) and CP002463 (pLS2). The version described in this paper is the first version. Prediction of protein encoding sequences and open reading frames (ORFs) were initially accomplished with PEDANT software suite [54]. The PEDANT genome database provides exhaustive annotation of nearly 3000 publicly available eukaryotic, eubacterial, archaeal and viral genomes. Gene prediction was performed with GenMark 2.8 [55]and Glimmer 3.0 [56]as implemented in the Pedant software suite. All ORF predictions were verified and modified by a blasting orfs to NCBI nrdb. Additionally, the predicted suite. All orf predictions were verified and modified by a Glimmer 3.0 [56]as implemented in the Pedant software suite [54]. The PEDANT genome database provides exhaustive annotation of nearly 3000 publicly available eukaryotic, eubacterial, archaeal and viral genomes. Gene prediction was performed with GenMark 2.8 [55]and Glimmer 3.0 [56]as implemented in the Pedant software suite. All ORF predictions were verified and modified by a blasting orfs to NCBI nrdb. Additionally, the predicted start codons of all ORFs were inspected manually using the Artemis program [57]. Clustered regularly interspaced short palindromic repeats (CRISPR) were identified with the web tool CRISPRFinder [36].

Phylogenetic tree
A phylogenetic tree on the basis of a multiple 16S rDNA alignment based similarity matrix was constructed by the neighbour-joining method [58] using the software package Bionumerics v6.5 (Applied Maths, Belgium). Unknown bases were discarded for the analyses. Bootstrapping analysis was undertaken to test the statistical reliability of the topology of the neighbour-joining tree using 100 bootstrap resamplings of the data.

Exopolysaccharide analysis
For production of EPS strain TMW 1.1304 was grown on mMRS containing 80 g l−1 of sucrose at 30°C for 24 h. To analyze the type of the polymer the EPS was precipitated by adding two volumes of ethanol (99%) and incubation at 4°C for 18 h. EPS was hydrolyzed with perehlic acid at 100°C for 3 h and sugar monomers were analyzed with HPLC as described by Waldherr et al. 2008 [28].
