Although climate change is considered to have been a large-scale driver of African human evolution, landscape-scale shifts in ecological resources that may have shaped novel hominin adaptations are rarely investigated. We use well-dated, high-resolution, drill-core datasets to understand ecological dynamics associated with a major adaptive transition in the archeological record ~24 km from the coring site. Outcrops preserve evidence of the replacement of Acheulean by Middle Stone Age (MSA) technological, cognitive, and social innovations between 500 and 300 thousand years (ka) ago, contemporaneous with large-scale taxonomic and adaptive turnover in mammal herbivores. Beginning ~400 ka ago, tectonic, hydrological, and ecological changes combined to disrupt a relatively stable resource base, prompting fluctuations of increasing magnitude in freshwater availability, grassland communities, and woody plant cover. Interaction of these factors offers a resource-oriented hypothesis for the evolutionary success of MSA adaptations, which likely contributed to the ecological flexibility typical of Homo sapiens foragers.

INTRODUCTION

Hypotheses linking environmental change with human evolution have focused on temporal correlations between global or regional climate change and major evolutionary benchmarks. For African hominin evolution, one approach is to identify how increased aridity, humidity, or climate variability induced by orbital forcing broadly coincided with, and thus potentially initiated, the emergence of hominin adaptations and speciation events over time (1–5). It is not yet clear, however, whether any of these general paleoclimate hypotheses account for critical transitions in hominin evolution. A continuing challenge is to connect climate and environmental records with water availability, food, and other ecological resources critical to energy acquisition, yet susceptible to changes that may undermine an organism’s existing adaptive strategies. Here, we integrate high-resolution drill core data with outcrop records from adjacent sub-basins in the southern Kenyan Rift Valley to examine how shifts in landscape-scale ecological resources could have influenced hominin adaptation during an interval of fundamental archeological and paleontological change in this region.

The sedimentary record recovered by the Olorgesailie Drilling Project (core ODP-LOLO12-1A) from the Koora basin (1.8°S, 36.4°E) provides evidence for changes in water availability, vegetation, and overall resource landscapes associated with the demise of the Acheulean—the longest enduring Paleolithic technology—and its replacement by early Middle Stone Age (MSA) technology as documented in the adjacent Olorgesailie basin (1.5° to 1.6°S, 36.4° to 36.5°E; Fig. 1). Olorgesailie preserves the oldest evidence currently known in East Africa of the permanent loss of the Acheulean (defined by handaxes and other large cutting tools) and the emergence of MSA behavioral innovations (6, 7). This transition involved new technologies, long-distance obsidian transfer indicating resource exchange among interconnected social groups, and the use of colorful materials potentially related to enhanced symbolic capability (Table 1).

The onset of these behavioral innovations in the southern Kenya rift occurred between 500 and 320 thousand years (ka) ago (Fig. 1) (8), an interval that overlaps the estimated time of genomic divergence between *Homo sapiens* in Africa and the Neanderthal-Denisovan clade in Eurasia (9). The oldest, widely acknowledged fossil evidence of *H. sapiens* (Jebel Irhoud, Morocco), dated roughly 320 to 300 ka old (10), coincided temporally with the oldest East African MSA evidence at Olorgesailie. Although other hominin species, such as *H. heidelbergensis* [or *H. rhodesiensis*, e.g., Kabwe, Zambia; (11)] and *Homo naledi* (12), were also present in Africa at this time, neither of these taxa is securely associated with MSA artifacts, whereas the MSA is widely associated from 300 ka ago onward with early *H. sapiens* (13, 14). Hominin remains from southern Kenya dated 397 to 334 ka old consist of poorly preserved teeth and a femoral shaft from Lainyamok (Fig. 1A), which are metrically consistent with early *H. sapiens* but otherwise cannot distinguish archaic and modern humans (15, 16). Other cranial remains of late middle Pleistocene age in eastern Africa typically combine *H. sapiens* and archaic traits, yet these finds are either poorly constrained chronologically (e.g., Eliye Springs KNM-ES 11693, Kenya) or <200 ka old (e.g., Guomde Formation KNM-ER 3884, Kenya; Eyasi 1 and 2, Ngaloba LH 18, Tanzania; Kibish Formation Omo 1 and 2, Herto BOU-VP-16/1, Ethiopia) [reviewed in (17)].

Our study does not presume that either the MSA or *H. sapiens* originated in the southern Kenya rift. This region, however, has yielded what is currently the oldest record with precise dating (8) where MSA behavioral innovations permanently replaced the Acheulean. In the southern Kenya rift, the Acheulean-to-MSA archeological transition was accompanied by a massive, ~85% turnover in mammalian species between ~394 and 320 ka ago (7). As part of the turnover, previously dominant megaherbivores disappear from the record (“megagrazers”: body mass > 900 kg), while smaller, water-independent, mixed grazing/browsing herbivores increased in abundance (Fig. 1D and table S1).

An important motivation of our study is that an erosional hiatus occurs in the Olorgesailie basin outcrop record between 500 and 320 ka ago—the interval in which the behavioral and faunal transitions described above took place (Figs. 1 and 2). A structurally controlled southward slope and faulting episodes that created rift sub-basins have been recognized for some time in the southern Kenya rift (18). We thus reasoned that a drill core in the Koora basin adjacent to and directly downstream from the Olorgesailie basin could recover...
Table 1. Comparison of Acheulean technology (typified by handaxes and other large cutting tools [LCTs]) and MSA technology. Behavioral and environmental comparison includes lithic source access and rock transport, pigment use, and environment evidence based on observations in the Olorgesailie basin (6–8, 34), located 22 to 24 km from the OLO12-1A drilling site. Predicted insolation dynamics (high or low climate variability) based on (5).

| Comparisons (Olorgesailie basin) | Acheulean Olorgesailie Fm. (1.2 Ma to 499 ka ago) | MSA lower Ottulelei Fm. (~320 to 295 ka ago) |
|----------------------------------|-----------------------------------------------|-------------------------------------------|
| Artifact/tool size               | Large tools, LCTs dominant                    | Smaller, diversified tools                |
| Focus of lithic source access    | Local volcanic rocks, coarse, and fine-grain (98%) | Fine-grain rocks (e.g., obsidian, chert, and fine-grain local volcanics) |
| Stone transport distances        | No more than 5 km                             | Obsidian transfer: 25 to 95 km, from multiple directions |
| Altered and used pigments        | No                                            | Yes                                       |
| Depositional regime (horst-graben formation) | Stable, aggrading system (lake/fluvial/floodplain) | Highly dynamic landscape (sub-basin cutting-and-filling) |
| East Africa insolation (precipitation dynamics) | Alternating high-low climate variability | Sustained period of strong climate variability |

RESULTS

The sediment core was recovered in the Koora basin at a location ~24 km south of the Olorgesailie outcrops that preserve evidence of the large shifts in hominin behavior and faunal communities discussed above. The core’s trachytic basement rock is overlain by a complex succession of diatomaceous, carbonate-rich, siliclastic, and volcaniclastic fluvial and mostly lacustrine sediments, with multiple intervals of pedogenic alteration (Fig. 2). Our analyses have yielded environmental data spanning most of the past 1 Ma, including, particularly, high-resolution data for the temporal window of interest between 500 and 300 ka ago. We focused on exploring changes in the availability of ecological resources by reconstructing vegetation dynamics, paleohydrology, and hydroclimatic signals.

Ecological indicators

The core datasets allow us to track the past availability of freshwater on the landscape, which is a limiting factor for most mammal species in eastern Africa and therefore strongly affects populations in the area (25). To examine past changes in water supply, we used a set of paleohydrological proxies including sediment stratigraphy, diatom assemblage data (transfer functions), x-ray fluorescence (XRF) elemental profiles, and x-ray diffraction (XRD) minerology (Fig. 3A). Diatom-based records of electrical conductivity (EC) and planktonic versus benthic taxa (diatom CA axis 1) were used to reconstruct changes in Koora basin salinity and relative lake depth (26), respectively (Fig. 3A and Fig. S3), thus reflecting the availability of potable water contained in a lake source. We integrate these paleohydrological records with evidence of 30 paleosols, each broadly estimated to represent subaerial exposure of ~50 to ~5000 years duration on the basis of soil maturity and structure [see Materials and Methods; (19)], which together indicate repeated lake-land transitions. Sedimentary structures such as burrows that formed in subaerially exposed sediments from Olorgesailie, in contrast with ≤5-km distance of stone transport typical of the Acheulean tool assemblages (Table 1) (6, 7). Integrating these data and observations with evidence of regional tectonism and landscape partitioning provides a framework for connecting, at high geochronological resolution, the sequence of changing resource landscapes with the critical transitions in hominin behavior and fauna.

Data compilations on human foraging behavior, which include more than 150 hunter-gatherer societies from low-latitude environments, show that diet, foraging range, group mobility, and size, among other adaptive characteristics, are systematically related to environmental setting (21–23). According to these ethnographic observations, hunter-gatherers tend to increase their investment in technology, expand their range of resource acquisition, and rely on distant social alliances and exchange networks in situations of heightened resource unpredictability and risk (23, 24). Given that these responses in modern human foragers have parallels in the archaeological innovations of the Olorgesailie MSA (6, 7), we examined the core record to test the hypothesis that decreased resource predictability could have been a factor in the early appearance of MSA adaptations in the southern Kenya rift. The specific question we address is whether MSA behaviors replaced the Acheulean in this region during a period of increased resource fluctuation, an ecological factor that could have more broadly shaped the emergence of observed adaptive responses of H. sapiens foragers.
Fig. 2. Stratigraphic and paleohydrologic relationships between the Koora basin, where the ODP-OL012-1A drill core was obtained (Fig. 1), and the Olorgesailie basin, where the transitions in Acheulean-MSA behavior and mammalian fauna are recorded. (A) Correlation between OLO12-1A z-prime core stratigraphy and the Olorgesailie basin outcrop record, based on dates in (7, 8, 19). The core’s stratigraphic column is corrected for rapid and instantaneous deposits with thick volcanoclastic layers (red color) and event deposits removed. The overall z-prime core thickness is therefore lower than that of the recovered core; see (19). Outcrop Land color code: orange, aggrading sediment; brown, stable land surface; red, burned zone. (B) Hypothesized reconstruction of basin history and drainage relationships of the Olorgesailie and Koora basins from 500 ka ago to present. The sequential maps show the connections between the two basins, based on sediment correlations and tephra dates, and illustrate increasing compartmentalization of this part of the southern Kenya rift over the past 500 ka (34). This reconstruction conforms to the present-day topography; the spatial extent of the Koora basin paleolake is approximate. Question marks denote uncertainties in lake extent in the northern Koora basin. Color code: blue, lake; white, eroding outcrops of the Olorgesailie Fm.; red-orange, major paleosol (base of Olkesiteti Mb., Oltulelei Fm.); purple, major volcanoclastic influx (Olkesiteti Mb, Oltulelei Fm.); orange, volcanoclastics plus fluvial siliciclastic sediments (Oltepesi Mb., Oltulelei Fm.). Red dots in the Koora basin mark the locations of drill cores.
Fig. 3. Paleoenviromental data from core ODP-OLO12-1A. Colored horizontal bars summarize intervals of similar paleoenvironmental conditions; darker to lighter colors represent lower to higher variability intervals. Vertical yellow bars denote paleosols (PSOLS), indicating lake desiccation. (A) Water availability data: XRD shows major mineral groups (zeolites; predominantly analcime and phillipsite). Correspondence analysis (CA) scores of diatom assemblage data indicate fluctuations in lake water depth. EC of paleolake waters are derived from a diatom transfer function (blue, fresh; green, brackish; red, saline; 2500 μS/cm assumed limit of potable water for humans). Ratio of silica and potassium counts from XRF analysis shows five-point moving average; high (low) values indicate high (low) diatom productivity (text S3) (88). (B) Vegetation dynamics data: Stable carbon isotope values of carbonate nodules (δ13Cpc) from paleosols; vegetation classes from (89). Tree cover density index (D/P) of phytolith assemblage data (30): higher values indicate dense woody cover; green dots denote absence of grass phytoliths. Stable isotope values of bulk sedimentary organic matter (δ13Corg; black) and proportion of C3 versus C4 plants from plant leaf wax isotopes (δ13Cwax; red). Phytolith index (Iph) from grass phytolith data indicate proportion of short (Chloridoideae) versus tall (Panicoideae) grasses (29). All datasets are plotted at their median age. Dots denote single data points; envelopes reflect 68% (dark) and 95% (light) confidence intervals (19). Continuity of data and uncertainty envelopes are interrupted at hiatuses, core gaps, and measurement gaps.
document periods of lowered water table down to several meters below the emergent land surface (table S2 and text S2). We measured the carbon isotopic composition of pedogenic carbonates ($\delta^{13}$C$_{org}$) from the paleosols and obtained values of between $-1.28$ and $2.03$ per mil (‰) (average 0.03‰), which consistently indicate local C$_4$ grasslands during subaerial intervals (Fig. 3B). On the basis of the combined evidence, we conclude that each emergent land surface represents a period of marked lake regression and local to lake-basin-wide desiccation. Multiple lithological transitions between lacustrine sediments and paleosols throughout the core can thus be explained by marked variations in water supply to the Koora basin.

Vegetation is also a critical resource for many mammal species, especially herbivores, and a primary determinant of habitat, dietary, and foraging opportunities. We reconstructed vegetation cover and composition on local to regional scales by using carbon isotopes of leaf waxes, bulk organic matter, and pedogenic carbonates ($\delta^{13}$C$_{wax}$, $\delta^{13}$C$_{org}$, and $\delta^{13}$C$_{pc}$) and also phytolith assemblage data (Fig. 3B) (see Materials and Methods). The carbon isotope data are interpreted in terms of the proportion C$_3$ to C$_4$ plants, with C$_4$ plants, mainly grasses, having higher water use efficiency adapted to arid conditions (27).

These carbon isotope–based proxies were necessarily obtained from different lithologies; they thus preserve vegetation signals representing different yet overlapping time periods and varied spatial scales. Whereas the $\delta^{13}$C signature of pedogenic carbonates reflects only a localized signal preserved in dry and exposed land surfaces lacking sediment input (i.e., no aggradation), these conditions resulted in poor preservation of leaf waxes and organic matter. Thus, leaf wax and bulk organic $\delta^{13}$C samples were extracted from lacustrine sediments. The bulk organic $\delta^{13}$C measurements contain a mixed signal of basin-scale terrestrial vegetation and aquatic biomass (e.g., algae) originating from the lake itself. The source area of bulk organic $\delta^{13}$C is smaller than that of the leaf wax $\delta^{13}$C samples because the transport of waxes is partly fluvial and partly aeolian (wax aerosols), and the latter can result in long-distance dispersal. Leaf waxes are primarily produced by terrestrial vascular plants; therefore, the sediment leaf wax $\delta^{13}$C signal reflects the past C$_3$/C$_4$ plant composition from the Koora basin and its catchment.

The phytolith data also record vegetation signals on local (during dry phases) to regional (fluvial transport during wet phases) scales. An advantage of including phytolith morphotypes in our analysis is that they can be resolved taxonomically (28, 29). From the phytolith assemblages, we determined the tree cover density index (D/P) and the phytolith index (Iph). The D/P ratio is the proportion of woody dicotyledons (D) over grasses (Poaceae, P), which we use to estimate woody plant cover on the paleolandscapes (30, 31). The Iph records the proportion of short (Chloridoideae) and tall grasses (Panicoideae) in savanna ecosystems, with values of $>20$ to 40% indicating short-grass dominance (29, 31). In Africa today, areas of higher water availability generally favor woody vegetation and/or tall grasses (Panicoideae), whereas arid conditions favor short grasses (Chloridoideae) (29), which allows us to link past vegetation composition with paleohydrology.

**A shift in ecological resources**

The core record exhibits mostly subdued variability in both the lacustrine and terrestrial datasets during its first ~500 ka, followed by a 400-ka-long interval of marked variability and ecological disruptions (Fig. 3). The division of the record into two major variability phases is also illustrated by a doubling of dry intervals of emergent land surface ($n = 9$ paleosols before 500 ka ago versus 20 paleosols after). Overall, the proxy data contain only weak orbital signals (11 to 17% of the variance), dominated by the 100-ka eccentricity period in the lake depth reconstruction (diatom CA axis 1), the XRF Si/K ratio, and D/P tree cover index (Fig. 4 and fig. S4).

Between ~1 Ma and 470 ± 15 ka ago, intermediate to deep freshwater lakes prevailed in the Koora basin as inferred from the diatom CA axis 1 and EC reconstruction (median EC <800 μS/cm; Fig. 3A). These lake phases were interrupted by nine emergent land phases represented by paleosols that lasted for ~1000 to ~5000 years (19). Most of these dry phases occurred between 780 and 590 ka ago. However, the combined duration of all nine dry episodes represents only ~5% of this 530-ka-long period based on the age model (19). The evidence indicates that freshwater was generally available in the Koora basin (Fig. 3A) during the period when Acheulean toolmakers were active at Olorgesailie.

A reliable freshwater supply would have sustained the predominantly water-dependent fauna of the region up to ~470 ka ago (Fig. 1D). Before the major faunal and archeological transitions (i.e., before 500 ka ago), intermediate values of the D/P tree cover index with a median of 1 (range, 0.2 to 36; Fig. 3B and fig. S5) indicate a mix of woody and grassy vegetation typical for African tall and short grass savannas (29). The stable isotope record for this interval shows depleted $\delta^{13}$C$_{org}$ values, ranging from $-24.9$ to $-27.7$‰ (average, $-26.4$‰), which are typical for C$_3$-dominated vegetation consistent with the D/P values of mixed vegetation. Coupled with evidence of intermediate-deep freshwater lakes, this vegetation composition points to relatively high moisture levels during the first 500 ka of the record. However, unexpectedly, we determine high Iph values with a median of ~60%, indicative of the concurrent predominance of short grasses (Chloridoideae; Fig. 3B), which typically prevail in arid grasslands and conditions of low soil moisture (29). The concurrent predominance of short grasses suggests that vegetation was influenced by factors beyond water availability (precipitation).

The prolonged freshwater period was disrupted at 470 ± 15 ka ago, initially by a ~5-ka dry episode followed by >60-ka interval of shallow and saline lake conditions (median EC, >5500 μS/cm; Fig. 3A), marking the transition to an interval of high environmental variability. During the critical time window between 500 to 300 ka ago, eight intervals of desiccation are recorded as paleosols, five of which are estimated to have lasted for ~5 ka each (Fig. 3). The intervals between these dry phases are approximately 68, 16, 19.5, 15, 5.5, 18, and 29 ka long, which conform partly with precessional frequencies and partly with nonorbital rhythms (fig. S4).

In concert with these more frequent wet-dry shifts, ecological resources began to fluctuate more widely by ~400 ka ago in both terrestrial and aquatic environments. Each of the lake phases during the critical window was distinct in terms of lake depth, salinity, diatom productivity, and composition (Si/K ratio; Fig. 3A and fig. S4), together with the more frequent subaerial intervals, these variable lake conditions point to large fluctuations in lake level and highly variable moisture supply. Between ~400 ± 5 ka and 320 ± 7 ka ago, the D/P tree cover index (0.1 to 10; median, 0.7) reveals rapid shifts between woody vegetation and grassland in line with varying water availability (Fig. 3B and fig. S5), consistent with assemblage-based ecological variability (fig. S6). This varying woody plant cover is also evident in larger fluctuations of $\delta^{13}$C$_{org}$ (−27.4 to −22.3‰) and $\delta^{13}$C$_{wax}$ (−34.5 to −22.9‰), suggesting shifts between C$_3$-dominated (100%)
and C₄-dominated (~70%) vegetation. The grassland composition as inferred by the Iph implies pronounced variation in tall- and short-grass dominance and complete turnover between these two grassland types after 350 ± 8 ka ago (Fig. 3B). From ~330 to ~250 ka ago, the Koora basin was apparently dominated by open grassland vegetation; few phytoliths of woody plants in this interval result in a low median D/P index of 0.15. These grasslands were either characterized by tall- or short-grass abundance but rarely of mixed composition.

The Olorgesailie Acheulean-to-MSA transition and the major faunal turnover thus coincided with the onset of an ecological landscape characterized by decreased reliability of potable water and increased variability of grassland vegetation-type beginning ~400 ka ago.
The shift from megagrazers to a predominance of smaller-bodied herbivores, with a higher proportion of browsers and mixed feeders, suggests that change in the mammal community favored organisms that could adjust to diverse and/or fluctuating vegetation and dietary resources (Fig. 1D). In addition, the more water-independent mammal taxa present in the fauna by at least 320 to 300 ka ago in the southern Kenya rift would have been more resilient to erratic freshwater availability.

Beginning ~250 ka ago, after these transitions occurred, the phytolith data indicate a shift toward tall grass dominance (median Ip, <20%) and the return of woody plants but with highly varying density. This vegetation change is also recorded by δ13C wax, which exhibits its overall largest fluctuations (between −32.9 and −18.4‰), thus suggesting a complete turnover between C3 and C4 plant dominance (Fig. 3B and fig. S5). Frequent ecological disruptions continued based on the recurrence of short dry intervals (n = 12, after 250 ka ago), strongly fluctuating lake depth, and more frequent saline lake conditions (Fig. 3A).

**DISCUSSION**

What factors could have led to the transitions in water and vegetation resources, the loss of megagrazers, and the replacement of Acheulean by MSA behaviors? Although orbitally paced climate variability is well documented in many East African paleoclimate records (1–5), evidence for orbital cyclicity in our core data is weak compared to the large, abrupt, and increasingly frequent landscape changes that we document. Our analyses show that rainfall variations during the past 1 Ma were influenced by orbital pacing, mainly the eccentricity cycle, but temporal changes in water availability and vegetation as recorded in the core cannot solely be explained by orbital forcing. Millennial-scale climate variations have been demonstrated in Northern Hemisphere mid–Pleistocene records [e.g., (32, 33)], but our indicator records at the current sampling resolution have not yet revealed this variability or temporal correlation with events documented at higher latitudes. The episodic prevalence of tall grasses (Fig. 3B; Ip), furthermore, is inconsistent with progressive aridity, another prominent hypothesis often invoked to explain hominin evolutionary change. By focusing on ecological resources rather than climate alone, our study suggests that a combination of geological, climatic, and ecological factors directly influenced fundamental shifts in hominin and faunal adaptations in the southern Kenya rift.

Previous geological observations document extensive faulting throughout the region after ~500 ka ago, manifested in the deep erosion of Olorgesailie Fm. outcrops to the north between ~499 and ~320 ka ago, and by drag-faulted sedimentary units that onlap horst walls after 499 ka ago at Olorgesailie and after ~397 ka ago at Lainyamok to the southwest (7, 16, 18, 34). Increased volcanic tephra input in the Koora basin beginning ~400 ka ago (Fig. S7) (19). One consequence of this tectonism was increased topographic relief and basin compartmentalization throughout the region (Fig. 1C and Fig. 2) (35). Tectonic development of the Koora basin’s graben morphology (Fig. 1, B and C) over time would have resulted in amplified lake level fluctuations due to higher sensitivity of graben-shaped lakes to changing moisture supply (36).

As a result, spatial heterogeneity in runoff, soil moisture, water availability, and woody/grassy vegetation proportions was accentuated, with basins of varying size and morphology potentially developing different sensitivities and divergent resource landscapes in response to climate variations. These interactions may account for contrasting environmental histories apparent in the adjacent Magadi and Koora basins. The Magadi drill core provides the only other relatively high-resolution environmental sequence in the region relevant to the past 1 Ma. Its vegetation record is interpreted as evidence of progressive aridification (37), whereas the higher-resolution record presented here shows increased tall-grass dominance, mixed woody/grassy vegetation, and fluctuations in C3 vegetation in the interval from 500 to 300 ka ago and after (fig. S8). This comparison indicates that, during the past 500,000 years, distinct ecological zones and resource landscapes developed over a distance of less than 20 km between the two rift basins (Fig. 1B). According to the relevant archeological data, distances of MSA obsidian transport were minimally ~25 to 95 km as straight-line measures, which further suggest that hominin foraging ranges and potential interactions among groups encompassed diverse resource landscapes from the southern to the central Kenya rift (6). This observation links the hominin and faunal transitions in southern Kenya with spatial heterogeneity in ecological resources in addition to the temporal variability shown here.

We note that the development of accentuated horst-graben topography also would have dissected and diminished the spatial continuity of grazing landscapes. Persistent high grazing pressure is known to transform broad areas of moist, wooded, and tall grass habitats into extensive short-grass grazing lawns (38–40). From ~1.0 Ma ago until the faunal turnover after 500 ka ago, the megagrazers of the southern Kenya rift had craniodental specializations and estimated body masses up to ~20% (e.g., the zebra Equus oldowayensis) to 400% (e.g., the baboon Theropithecus oswaldi) larger than their modern counterparts (41, 42), which together suggests a unique grazing community that had the capacity to establish and sustain short-grass grazing lawns despite the prevailing moist conditions (39, 40).

We propose that the megagrazer decline and emergence of a different suite of mammal species was a response to a more spatially fragmented and fluctuating resource base, which began ~400 ka ago and thus within the critical window of faunal and archeological change (Fig. 5). A combination of factors including accentuated topographic relief, climate variability, hydrological subdivision of the region, and fragmentation of vegetation types could have created an interactive cascade that diminished megagrazer populations in the region. This would have put specialized grazers dependent on predictable short-grass and freshwater availability at a disadvantage relative to mixed feeders and water-independent browsers, which increased between ~400 and 320 ka ago (Fig. 1D) (8). Small obsidian points with retouched bases recovered from Olorgesailie archeological sites are suggestive of projectile armaments dated ~320 to 307 ka ago (6) and thus potentially indicate hominin predation as a possible influence on herbivore turnover in this region. Since the definitive loss of megagrazer species in the region is recorded at 397 to 334 ka ago [Lainyamok fauna; (8, 43)], the Olorgesailie MSA stone points could, however, reflect a technological innovation for hunting smaller prey following the loss of megagrazer species (see Fig. 1D).

We further suggest that compartmentalizing of the southern Kenya rift into horst/graben-delimited basins with quasi-independent resource dynamics also favored the transition to MSA behavior. Even as mammalian populations experienced increased fragmentation of vegetation types due to topographic partitioning of the landscape, evidence of widespread obsidian exchange networks by ~320 to 295 ka ago (6, 8) implies that the MSA hominin groups actually became more connected across the larger region. This response was potentially...
critical to their evolutionary success in the changed resource regime. We hypothesize that MSA technological innovations and distant resource exchange, sustained by symbolic communication, reflect an ability to respond to increased instability in resource landscapes through risk mitigation, an adaptive strategy ultimately characteristic of human foragers today (23, 24).

On the basis of our study, concurrent reshaping of hominin behavior and the faunal community can be understood as distinctive responses to similar ecological stresses. We conclude that although MSA adaptations may have originated elsewhere, they took hold in the southern Kenya rift between 400 and 320 ka ago as a result of heterogeneity in selective conditions induced by the marked shift to a temporally and spatially varied and less predictable resource landscape, favoring hominin populations with resilient adaptations. Early evidence of this response suggests that fundamental aspects of human adaptability had emerged by the time of our species’ African origin.

Our study prompts a wide range of questions for future investigation. We do not address here the continent-wide demise of the Acheulean and its replacement by the MSA but offer a resource landscape hypothesis that could be tested in other parts of Africa. Last records of the Acheulean occurred at various times in other African regions [e.g., (44)], later than in the southern Kenya rift. The onset of the MSA, furthermore, is recorded at varying times in different places, and MSA sites across the continent are associated with diverse environmental settings (14, 45). In our study, the oldest documented transition from Acheulean to MSA in eastern Africa occurred in the context of repeated environmental disruptions. The hypothesis that we present, which is limited to a conjunction of factors in the southern Kenya rift, should be examined elsewhere to see whether the MSA flourished at the expense of the Acheulean under similar circumstances of ecological disturbance. We recognize, however, that once MSA behaviors evolved, the adaptive flexibility they conferred would have been advantageous and sustained in other locations where the MSA spread, including in relatively stable habitats.

Integration of resource dynamics with regional tectonic and ecological history, as exemplified by our study, also suggests a new direction in the search for causal processes that shaped human evolution. Evolutionary adaptation entails not only the origin of behavioral variations (7) but also their increase within a population and spread across a wider geographic area. Studies of how environment may initiate evolution, therefore, need to further address the processes that underlie adaptive change rather than assume, for example, that correlations between evolution and either aridity, moisture, or variability provide a useful explanatory hypothesis for any given change (5). Robust ecological theory as applied to human hunter-gatherers and mammal herbivores provided the framework for investigating the potential environmental influences on the hominin and faunal adaptations described here. We intend this approach to be useful in motivating future research on how environmental dynamics may have led to critical transitions in human evolution.

**MATERIALS AND METHODS**

**Bayesian age model (C.B.K.)**

To constrain the absolute chronology of the ODP-OLO12-1A core, a high-resolution age-depth model (fig. S2) was constructed using a...
Bayesian stochastic sampling approach to combine quantitative age constraints from Ar-Ar geochronology, semiquantitative minimum estimates for the duration of observed exposure surfaces (depositional hiatuses), and the absolute constraint of stratigraphic superposition. As described in (19), this Markov chain Monte Carlo model uses the Metropolis algorithm to estimate the posterior age distribution for each centimeter of core depth. At each step of the Markov chain, the previous age-depth model is perturbed by a symmetric Gaussian proposal distribution, checked for stratigraphic superposition, and evaluated against the combined quantitative constraints. Since adjacent proposals are highly correlated, this model was run with a burn-in of 20,000,000 steps, and a sieved stationary distribution collected over the subsequent 500,000,000 steps of the Markov chain.

Age and proxy uncertainty analysis (S.R. and Y.G.)
Paleoenvironmental proxy data were translated into the time domain considering both proxy and age model uncertainties by calculating uncertainty envelopes (shown in Fig. 3). Envelope width along the time direction (x axis) represents absolute age uncertainty based on the age model. Envelope height in the proxy direction (y axis) represents the analytical uncertainty of the proxy dataset. These uncertainty envelopes were generated by using the full age model output: For each proxy data point, its z-prime depth was assigned to the complete corresponding sieved age distribution (n = 25,000) of the full age model at sample depth. (Fig. S2 shows the age model uncertainties on the z-prime depth scale.) The analytical uncertainties of the proxy data were assumed to have a normal distribution. These two individual uncertainties, in time domain (age model) and proxy domain (analytical uncertainty), were used to generate two-dimensional histograms for each data point. The obtained probabilities were then combined to composite probabilities per continuous section of the dataset. The environmental proxy records were treated as discontinuous sections wherever the record was interrupted either by a paleosol occurrence (huiatues), by absence of core recovery (depth gaps), or by measurement gaps. A conservative discontinuity criterion was further applied if neighboring data points were too remotely spaced, either in time axis (threshold of 20 ka) or in the depth axis (threshold of 10 m). For each obtained continuous time interval, the obtained probability densities of individual data points were merged into a composite probability. The resulting 68 and 95% confidence envelopes were ultimately extracted from the obtained composite probability distributions. All the processing was undertaken using MATLAB (46).

Spectral analysis (S.R. and P.d.M.)
To analyze orbital variability within the time series, Lomb-Scargle power spectra were calculated because of their ability to work with unevenly spaced data as represented in this drill core. The absolute uncertainty of the age model was included by converting the proxy data into the time domain for each individual z-prime–time distribution of the full age model (n = 25,000). Lomb-Scargle power spectra were then calculated for each of the resulting time series of a specific proxy (Fig. 4). Individual spectra (n = 25,000) were stacked to create one representative spectral power density plot. This density plot shows the frequency spectrum of the proxy data, taking into account time uncertainty in the full age model. Higher densities in the stacked spectrum denote spectral powers, which are consistent across the full age model.

Diatoms (R.B.O.)
Diatom samples were collected every 30 cm and where facies changed, with sampling intervals reduced to 10 cm in relatively pure diatomites. Subsequent resampling of diatomaceous deposits was carried out to reduce intervals for these sediments to 10 to 12 cm. Samples were weighed and placed in a Calgon solution to assist dispersion. After washing with distilled water, 10% HCl was added to remove carbonates followed by further washing. Subsequently, 30% H2O2 was added, followed by washing. In the last stage, a known number of microspheres (8 µm in diameter) were added to enable quantitative counting. Smear slides were prepared using Naphrax. A minimum of 400 diatoms were counted, except where diatoms were rare in which case all frustules were tallied. Diatoms were included in counts when more than half of a frustule was present. Apices were counted for fragmentary long thin fragile taxa. Diatoms were identified at x1000 magnification with the supplementary aid of a LEO 1530 field-emission scanning electron microscope. Identiﬁcations used standard taxonomic works and, especially, Gasse (47, 48). Correspondence analyses (CAs) were carried out using CANOCO 4.5 with taxa that formed ≥3% in at least two samples or ≥10% in at least one sample, included in analyses (n = 476). CA axis 1 tracks water depth, indicated by a high correlation with percentage of planktonic taxa, with negative values associated with abundant Aulacoseira spp. and rare Stephanodiscus (r = -0.959, P < 0.001) and positive values associated with benthic taxa (shallow). The percentage variance explained by CA axis 1 is 68%. Environmental reconstructions were performed using ERNIE software v. 1.2. EC for each sample (n = 476) was determined using the European Diatom Database (EDDI) “Combined Salinity Dataset”, and “Locally weighted Weighted Averaging.”

Phytoliths and pollen (R.K., R.D., and S.M.R.)
Two hundred seventy-two phytolith samples, 2 to 3 cm3 in volume, were collected at 48-cm intervals with finer sampling at ±10-cm interval depending on core lithology. Samples were processed using a modified heavy liquid floatation (49) as outlined in (50): (i) dissolution of carbonates with HCL, (ii) oxidation of organic matter using HNO3, (iii) heavy liquid floatation using Sodium Polytungstate at density of 2.4 g/cm3, and (iv) gravitational removal of clay. The recovered fraction was mounted on microscope slides using Entellan New medium. Freshly mounted slides were viewed under an Olympus BX52 microscope at ≈400 magniﬁcation for three-dimensional observation and counting. Because most samples had low phytolith abundances, phytoliths >5 µm in diameter in each sample were counted and classiﬁed with aim of attaining a minimum of 200 grass short silica cells (GSSCs) to acquire a statistically robust dataset. Identiﬁcation and classiﬁcation of phytoliths largely followed the International Code of Phytoliths Nomenclature (51) with reﬁned GSSCs classiﬁcation based on (52–54) and with further consultation of other published studies (28, 50, 55–70). Phytolith data interpretation was based on two approaches. First, abundance diagrams generated using Tilia program (71) showed variation in phytolith assemblages throughout the core, which provided information about vegetation structure through time (50). Second, phytolith indices were computed to determine changes in vegetation composition and climatic conditions. Two phytolith indices were calculated: The D/P tree cover index is the ratio of woody dicotyledons to all grasses and indicates changes in tree cover density through time (n = 218) (30). The index was computed by dividing rough globular phytoliths with the sum of Poaceae phytoliths from the subfamilies Panicoideae,
Chloridoideae, Arundinoideae, and Aristidoideae (dumbbell, cross, saddle, point-shaped, and fan-shaped types). The Phytolith index (Iph) presents the relative proportion of Chloridoideae (aridity affinity C₄ short grasses) versus Panicoidae (moist affinity C₃ tall grasses) and was used to investigate temporal changes in this water availability indicator (n = 183). The Iph was computed as the ratio of Chloridoideae (saddle morphotype) to the sum of Chloridoideae and Panicoidae (saddle, cross, and dumbbell morphotypes) (29). Cores were also sampled for pollen. Samples were processed at Ghent University in Belgium following standard palynological procedures for concentrating pollen grains (72). Slides mounted for pollen counts were examined at the National Museums of Kenya, Department of Earth Sciences. Pollen was investigated using a Leitz microscope at ×400. Pollen preservation was very poor. Most slides had no pollen, but in rare cases, one or two grains were observed. Poor preservation might have been influenced by oxidation, high temperature, and low organic matter content, among other external factors.

Identification of hiatuses and paleosols (E.J.B.)
Thirty hiatuses marked by paleosols occur in core OLO12-1A and range from weakly to moderately develop. These paleosols are identified by diagnostic soil features such as bioturbation, soil ped, horizonation, and pedogenic carbonate. The top of each paleosol was identified by a lithologic change and loss of ped structure, and the bottom of each paleosol by the return of identifiable parent material lithology such as laminated lacustrine sediments. The presence or absence and degree of development of these features allows for classification of the paleosols using U.S. Department of Agriculture Soil Taxonomy as paleo-Entisols, paleo-Inceptisols, and paleo-Vertisols (73). The core ODP-OLO12-1A Entisols are very weakly developed soils with little or no evidence of soil horizons, and they often contain relict bedding. The Inceptisols are more strongly developed than Entisols with soil horizonation and ped formation but lack distinguishing features that would allow them to be classified as another soil order. The Vertisols are clay-rich soils with cracks, pedogenic slickensides, and other vertic features that form as a result of shrinking and swelling of clays during wetting and drying. These diagnostic features also allow for classification of these paleosols into a paleosol maturity index modified from (74). This paleosol maturity index can then be related to approximate the duration of pedogenesis as certain soil features form at different time scales. For additional discussion of the paleosol characterization and estimates of duration for the age modeling, see (19).

δ¹³C wax and δ¹³C org (J.M.R., R.L., K.U., and P.d.M.)
We measured the carbon isotopic composition of terrestrial leaf waxes (n = 37) following the protocol outlined in (75). Lipids, which include leaf waxes, were extracted from freeze-dried and homogenized bulk sediment using a DIONEX Accelerated Solvent Extractor 350 with dichloromethane:methanol (9:1). The lipids were separated into neutral and acid fractions over an amino propylsil gel column using dichloromethane:isopropanol (2:1) and ether:acetic acid (24:1). The acids were methylated using acidified methanol of known isotopic composition (J.W.M., N.E.L., and E.J.B.). Measurements of the δ¹³C of terrestrial leaf waxes (n-C30 acids of −32.9‰) indicate negligible offsets between these homologs, allowing us to apply the end member δ¹³C wax compositions to the n-C30 acids. Carbonate was collected at least 50 cm below the top of each paleosol (or a conservative estimate of the top) to ensure that δ¹³C values of pedogenic carbonates (δ¹³C pc) reflect
the isotopic composition of vegetation and not that of atmospheric CO₂ (85). These carbonates, which were at various stages of development, were sampled throughout the Bk horizons of moderately well-developed paleosols, with ped development and horization caused by the dissolution of carbonate and reprecipitation at depth. These Bk horizons showed increased Ca content at depth in scanning XRF unrelated to the parent material. These carbonates were also identified as pedogenic in origin by their size (≤2 cm), micritic texture, and the incorporation of soil matrix into the carbonate material as they grew over time. Pedogenic carbonates less than 50 cm below the top of the paleosol, larger than 2 cm, or with sparry textures were excluded from analysis to avoid any potential for diagenetic alteration. Samples were powdered, homogenized, and dried below the top of the paleosol, larger than 2 cm, or with sparry textures.

These Bk horizons showed increased Ca content at depth in scanning XRF unrelated to the parent material. These carbonates were also identified as pedogenic in origin by their size (≤2 cm), micritic texture, and the incorporation of soil matrix into the carbonate material as they grew over time. Pedogenic carbonates less than 50 cm below the top of the paleosol, larger than 2 cm, or with sparry textures were excluded from analysis to avoid any potential for diagenetic alteration. Samples were powdered, homogenized, and dried at 40°C for 24 hours before analysis. Powders were digested in 100% phosphoric acid at 70°C in single reaction vessels using a NuCarb device. Carbon and oxygen isotope ratios of the resultant CO₂ were analyzed on a Nu Perspective gas source IRMS at the University of Michigan, Ann Arbor. Although not highlighted in this paper, δ¹³C and δ¹⁸O values of these samples are also reported here for completeness. A calcite working standard was measured every sixth sample and at the beginning and end of each analytical run, yielding a standard deviation of 0.03‰ (1σ) for δ¹³C and 0.11‰ (1σ) for δ¹⁸O, where δ = [Rsample/Rstandard – 1] × 1000. Carbon and oxygen isotope ratios of all samples were normalized via two-point linear calibration using international standards NBS-18 (δ¹³C = −5.014‰; δ¹⁸O = −23.2‰) and NBS-19 (δ¹³C = 1.95‰; δ¹⁸O = −2.20‰). For each paleosol with pedogenic carbonate, powders from two to nine unique carbonate samples were analyzed. Pedogenic carbonate samples include distinct nodules collected at discrete depths in the core and aggregates of less indurated carbonate material collected over 3- to 25-cm intervals within a single Bk horizon, as denoted in sample IDs. Each unique sample was analyzed in duplicate, yielding a mean intersample difference in δ¹³Cpc of 0.14‰ and δ¹⁸Op of 0.17‰. The mean δ¹³Cpc values and 1σ SDs of the analyses from these multiple nodules are plotted in Fig. 3. All δ¹³Cpc and δ¹⁸Op values are reported in ‰ relative to the VPDB standard. Age designations for mean pedogenic δ¹³Cpc values are shown at the midpoint of paleosol age durations.

X-ray diffraction (N.R. and D.D.)

Samples for XRD analysis were collected at 48-cm intervals and at higher resolution within sections of laminated lacustrine muds. A total of 402 samples were oven dried at 40°C for 48 hours and then ground to fine powder using ball and pestle impact grinders or mortar and pestle. At Georgia State University, the bulk mineralogy of core material was analyzed by powder XRD using a Panalytical X’pert Pro MPD using CuKα radiation, in the range 5°–70° 2θ, operating at 45 kV and 40 mA with a total scan time of 30 min. Powder diffraction patterns were analyzed using PANalytical High Score software suite with reference to PDF-2 database (86, 87).
