Monitoring and kinetic analysis of the molecular interactions by which a repressor protein, PhaR, binds to target DNAs and poly[(R)-3-hydroxybutyrate]

Miwa Yamada1,4, Shuntaro Takahashi2,5, Yoshiokata2, Yoshiharu Doi3 and Keiji Numata1*

Abstract
The repressor protein PhaR, which is a component of poly[(R)-3-hydroxybutyrate] granules, functions as a repressor of the gene expression of the phasin PhaP and of PhaR itself. We used a quartz crystal microbalance to investigate the binding behavior by which PhaR in Ralstonia eutropha H16 targets DNAs and amorphous poly[(R)-3-hydroxybutyrate] thin films. Binding rate constants, dissociation rate constants, and dissociation constants of the binding of PhaR to DNA and to amorphous poly[(R)-3-hydroxybutyrate] suggested that PhaR bind to both in a similar manner. On the basis of the binding rate constant values, we proposed that the phaP gene would be derepressed in harmony with the ratio of the concentration of the target DNA to the concentration of amorphous poly[(R)-3-hydroxybutyrate] at the start of poly[(R)-3-hydroxybutyrate] synthesis in R. eutropha H16.

Keywords: Polyhydroxyalkanoate, Autoregulator protein PhaR, Kinetic analysis, Ralstonia eutropha H16

Introduction
Polyhydroxyalkanoate (PHA), an eco-friendly and biodegradable polyester, is synthesized by a variety of bacteria, as their intracellular storage material for carbon and energy (Doi et al. 1995; Steinbuchel and Fuchtenbusch 1998; Sudesh et al. 2000). In bacterial cells, PHA forms granules that are covered with a layer composed of proteins and phospholipids (Potter et al. 2002). The most abundant constituent of this layer is phasin (PhaP). The presence of PhaP on the surface of PHA granules contributes to the reduction in size of PHA granules as well as to the slight enhancement of PHA production (Kojima et al. 2006; Potter et al. 2002; Potter and Steinbuchel 2005). Recently, the ability of PhaP to bind to a hydrophobic surface was used to develop methods for protein purification, drug delivery, and tissue engineering applications in in vitro experiments (Backstrom et al. 2007; Banki et al. 2005; Wang et al. 2008). In the cells of microorganisms, a repressor protein PhaR regulates the expression of phaP and phaR. PhaR has also been reported to sense the presence of PHA and to interact with nascent PHA granules, resulting in the derepression of phaP expression (Potter et al. 2002; Potter and Steinbuchel 2005). The presence of genes homologous to PhaR and PhaP in the genomes of various PHA-producing bacteria suggests that a similar regulatory system by PhaR is likely to exist in PHA-producing bacteria (Eugenio et al. 2010; Kojima et al. 2006; Maehara et al. 2002; Yamada et al. 2007; Yamashita et al. 2006). This regulatory system of PHA production through phaR and phaP expression can be applied in a two-hybrid system for protein-protein interaction (Wang et al. 2011). Therefore, understanding of the regulatory system provides meaningful benefit to not only basic science but also applications in various fields such as industry and medicine.

In previous studies, the binding behaviors of PhaR to target DNA (including the promoter region of phaP) and to melt-crystallized thin films of poly[(R)-3-hydroxybutyrate] [cr-P(3HB)] were investigated using surface plasmon resonance (SPR) and quartz crystal microbalance (QCM) measurements (Yamada et al. 2007; Yamashita et al. 2006). However, kinetic parameters such as the binding rate...
constant \((k_{on})\) and dissociation rate constant \((k_{off})\) by which PhaR targets DNA and P(3HB) have not been determined thus far. These kinetics and stoichiometric analyses will contribute new insights into the behavior of PhaR in the regulatory system of \(phaP\) expression.

In order to determine the precise kinetic parameters, we selected a multichannel QCM sensing system to monitor the binding reaction of PhaR from \(Ralstonia\ eutropha\ H16\) to target DNAs (including the promoter regions of \(phaP\) and \(phaR\)) and thin films of amorphous P(3HB) [am-P(3HB)] derived from atactic P(3HB). This is because the P(3HB) native granule is composed of am-P(3HB).

Recently, the regulatory system of PHA production through \(phaR\) and \(phaP\) expression has been applied in studies of protein-protein interaction, protein purification, drug delivery, and tissue engineering. The insights gained into this regulation mechanism in this study have the potential to improve applications in white biotechnology.

We have determined kinetic parameters based on mass changes on the DNA-immobilized and am-P(3HB)-coated QCM oscillators, and discuss the binding behavior of PhaR with target DNA and am-P(3HB).

**Methods**

**Expression and purification of autoregulator protein PhaR**

All chemical reagents were purchased from Wako Pure Chemicals (Osaka, Japan). The \(phaR\) gene from \(R.\ eutropha\ H16\) was cloned using a TOPO TA cloning Kit (Invitrogen, Carlsbad, CA) with the forward primer 5’-CACCATGGCCACGACCAAAAAAGG-3’ and reverse primer 5’-TTACTTCTTGTCCGGCTGGT-3’. The resultant plasmid is referred to as pET100/D-TOPO-PhaRRe. The expression of the \(phaR\) gene was driven by the T5 promoter, which is inducible with isopropyl-\(\alpha\)-D-thiogalactopyranoside (IPTG). The constructed plasmid was introduced into \(Escherichia\ coli\) BL21(DE3). Transformants were grown in 1200 mL of Luria-Bertani medium containing ampicillin (100 \(\mu\)g/mL) and kanamycin (50 \(\mu\)g/mL). They were cultivated at 30°C until the OD_{600} of the culture reached 0.5. After the addition of IPTG (final concentration of 1 mM), the transformants were grown for an additional 5 h. The cells were then harvested and washed with chilled buffer A (50 mM sodium phosphate (pH 8.0) containing 300 mM NaCl and 10 mM imidazole), and were suspended in 60 mL of the same buffer. The suspension was stored at \(-80^\circ C\) until use. The suspension was thawed on ice and disrupted by sonic oscillation, also on ice. The cell debris was then removed by centrifugation at 15000 \(\times\) g for 60 min at 4°C, and the supernatant was collected for purification. The experiments were carried out at 4°C throughout the purification steps. The crude extract was shaken gently with nickel-nitrilotriacetic acid agarose (Qiagen, Valencia, CA) for 1 h. The mixture was then poured into a column.

The column was washed with buffer A containing 20 mM imidazole, and then the His-tagged protein was eluted with buffer A containing 250 mM imidazole. The eluates containing PhaR were dialyzed against 10 mM HEPES (pH 7.4) containing 150 mM NaCl and 3 mM EDTA and stored at \(-80^\circ C\). The protein concentration was determined using a Bio-Rad Protein Assay Kit (Bio-Rad, Hercules, CA) with bovine serum albumin as the standard. Proteins were separated by sodium dodecyl sulfate (SDS)-12.5% polyacrylamide gel electrophoresis (PAGE) and stained with Coomassie brilliant blue (CBB) R-250 (BioRad) as described by Laemmli (Figure 1).

**Calibration of 27-MHz QCM in aqueous solution**

The QCM apparatus was an AFFINIX Q4 (Initium Co., Ltd., Tokyo, Japan) with 4 500-\(\mu\)L cells equipped with a 27-MHz QCM plate (8.7 mm diameter quartz plate and 5.7 mm² area Au electrode) at the bottom of the cell and a stirring bar with a temperature control system (Takahashi et al. 2007; Takahashi et al. 2008). The relationship between mass and frequency changes in aqueous solutions when DNAs and/or proteins were immobilized onto the QCM was calibrated by comparing it against values in the air phase. One Hz of frequency represents a 0.10 ng cm\(^{-2}\) mass increase on the QCM plate. The noise level of the 27-MHz QCM was ±2 Hz in buffer solutions at 25°C, and the stability of the frequency was ±2 Hz for 1 h in buffer at 25°C.

Preparation of the DNA-Immovlized QCM Oscillator

The structures of the biotinylated oligonucleotides used in this study are summarized in Table 1: they consisted of 5-biotinylated dsDNA (50 bp) containing a site recognized by PhaR dsDNA (phaP promoter region DNA and phaR promoter region DNA) and no-site dsDNA (control DNA). Oligonucleotide duplexes were formed by mixing a biotinylated strand and its complementary strand in a solution of 10 mM Tris–HCl (pH 7.8), 1 mM EDTA, and 200 mM NaCl, and then boiling for a few minutes, followed by cooling to room temperature over 1 h. These oligonucleotides were immobilized on a cleaned Au electrode of the QCM using biotin-avidin linkage according to the methods described in previous papers (Okahata et al. 1998). The amount of immobilized DNA was maintained at 191 ng (0.55 – 0.02 pmol) cm⁻², which corresponds to 1% coverage of the Au surface (5.7 mm²). This would allow sufficient space to accommodate the binding of a large enzyme molecule.

Preparation of P(3HB) thin films

QCM oscillators were washed with a freshly prepared Piranha solution of H₂O₂/H₂SO₄ (1/3 v/v) and were rinsed several times with Milli-Q water. (Caution: Piranha solution is very oxidative and dangerous, and direct contact should be avoided). Thin films of P(3HB) were prepared on the QCM oscillators by casting 300 μl of chloroform solutions (1.0 wt%) of the polymers on a spin-coater at 4000 rpm under dry air.

Reactions in the DNA-immobilized or am-P(3HB) coated QCM oscillator

Enzyme reactions in a DNA-immobilized or am-P(3HB) coated QCM cell were performed with 500 μl of assay buffer (10 mM HEPES (pH 7.4), 150 mM NaCl, and 0.002% Tween 20). The frequency changes in response to the addition of enzymes were then followed over time. The solution was vigorously stirred to avoid any effects from the slow diffusion of the enzymes. The stirring did not affect the stability or magnitude of the frequency changes.

Results

In order to measure the binding behavior of PhaR to 5'-biotinylated dsDNAs (50 bp), the DNA fragments with phaR-binding sequences (the promoter regions of phaR and phaP) and a non-specific sequence (negative control) were immobilized on the electrode of a QCM by biotin-avidin linkage, according to methods outlined in previous papers (Matsuno et al. 2001; Okahata et al. 1998). PhaR was purified using the His-tag purification system, and the purity of PhaR was confirmed by SDS-PAGE (Figure 1). The binding behaviors of PhaR to the DNA fragments were monitored. Figure 2A shows a typical frequency decrease (mass increase) as a function of time, in response to the addition of PhaR. PhaR mainly bound to the DNA containing the phaP promoter region (curve a), and barely bound to the DNA containing the phaR promoter region (curve b) and the control DNA (curve c). Figure 2B shows that the amount of the bound PhaR (Δfm) followed a saturation curve as a function of the PhaR concentration ([PhaR]). These binding curves formed a sigmoid curve.

Next, we attempted to determine the kinetic parameters (k_on, k_off, and K_d values) of the binding of PhaR to DNAs. The process by which PhaR binds to the DNAs is described by Equation 1 (Okahata et al. 1998). The amount of the DNA/PhaR complex ([DNA/PhaR]) formed after the injection is given by Equations 2 and 3. The fitting curves of the decreases in frequency at various PhaR concentrations gave the relaxation time (τ) and the relaxation rate (τ⁻¹) of PhaR binding. When the concentration of PhaR increased from 2.5 to 10 nM, the amount of PhaR bound to the DNA increased (Figure 3A). In addition, the τ value decreased with the concentration of PhaR. The 1/τ value at each PhaR concentration was plotted against the concentrations of PhaR, according to Equation 4 (Figure 3B). The PhaR binding and dissociation rate constants (k_on and k_off) were obtained from the slope and the intercept of Equation 4, respectively. The K_d values were obtained from the ratio k_off/k_on. The kinetic parameters, k_on, k_off, K_d, for the target DNAs and control DNA are summarized in Table 1.

Table 1: Kinetic parameters for the binding of PhaR to DNAs and P(3HB) on the 27-MHz QCM

| Targets       | DNA sequence                  | k_on (10⁻⁴ M⁻¹ s⁻¹) | k_off (10⁻³ s⁻¹) | K_d (10⁻⁷ M) |
|---------------|-------------------------------|---------------------|-----------------|-------------|
| Control DNA   | 5’bio-TCGTTTAAGAGCGGTATTTTCTCTTACCGTAGGACACCTAAC-3’ | 0.4                 | 0.7             | 18          |
| phaP1 promoter| 5’bio-GGCGCATTTGTTATGTCGGCGGAACATCTATCTATTATTTAGGGCGGCC-3’ | 6.0 ± 0.4           | 1.7 ± 0.4       | 3.2 ± 0.9   |
| phaR promoter | 5’bio-TCACCGGTTTACCGCATGCGGGGCGGCTAAGACAAACACACCGCGCGG-3’ | 0.5                 | 0.9             | 18          |
| am-P(3HB)     | 7.0 ± 3.8                     |                     |                 |             |

*1 10 mM HEPES buffer solution (pH 7.4) containing 150 mM NaCl and 0.002% Tween 20, 25°C. *2 5’-biotinylated dsDNA immobilized on an avidin-covered QCM plate.

Amorphous-P(3HB) thin film was prepared by casting chloroform solution (1.0 wt%) of the isotactic P(3HB), (S)-3-hydroxybutyrate. *3 The bold type indicates the DNA binding site of PhaR revealed by DNase I footprinting (4). *4 k_on and k_off were obtained from Eq. 4. *5 K_d was calculated as k_off/k_on. *6 The data are from 2 independent experiments. *7 Amorphous-P(3HB): the data are from 3 independent experiments. *8 K_d value could not be calculated due to a negative k_off value.
We also investigated the binding of PhaR to P(3HB) granules in microorganisms using a QCM sensor coated with am-P(3HB) (Figure 4A). This is because the P(3HB) native granules are mainly composed of am-P(3HB). The amount of PhaR bound on am-P(3HB) thin films increased when the concentration of PhaR increased from 1 to 15 nM (Figure 4B and C). Interestingly, as with the binding curve against the target DNA, the binding curve against am-P(3HB) exhibited a sigmoid curve. These results indicated that PhaR bound to P(3HB) in a similar manner as to DNA. The kinetic parameters \( k_{on} \) and \( k_{off} \) were calculated from Equations 1 to 4 (Figure 4D and Table 1). The \( k_{on} \) value for am-P(3HB) \( (k_{on} = 7.0 \pm 3.8 \times 10^4 \text{M}^{-1} \text{s}^{-1}) \) showed no significant difference from that for DNA containing the \( \text{phaP} \) promoter region \( (k_{on} = 6.0 \pm 0.4 \times 10^4 \text{M}^{-1} \text{s}^{-1}) \).

**Discussion**

In order to understand the regulatory system governing PHA production in detail, we investigated the binding behaviors of PhaR to the target DNA (containing the
promoter region of \textit{phaP}) and to P(3HB), using QCM measurements. Regarding PhaR-DNA binding, Figure 2A shows that PhaR mainly bound to the DNA containing the \textit{phaP} promoter region (curve a), and barely bound to the DNA containing the \textit{phaR} promoter region (curve b) or to the control DNA (curve c). The binding curve of PhaR to the \textit{phaP} promoter region showed sigmoid curve, implying that PhaR binds to target DNA in a cooperative reaction. The SPR analysis of PhaR-DNA binding in previous studies was not capable of monitoring the initial binding of PhaR, because the concentration of PhaR (10 $\mu$M) was higher than in the present experimental conditions (2.5 to 10 nM) (Kojima et al. 2006; Maehara et al. 2002). The higher binding affinity of PhaR to the \textit{phaP} promoter region accorded with the results of gel-mobility-shift assays (Maehara et al. 2002). The DNA fragments with the \textit{phaP} promoter region shifted at a lower concentration of PhaR compared to the DNA fragments that contained the \textit{phaR} promoter region (Potter et al. 2002).

The binding rate constant for the DNA containing the \textit{phaR} promoter region ($k_{\text{on}} = 0.5 \times 10^4$ M$^{-1}$ s$^{-1}$) was similar to the parameters for the control DNA ($k_{\text{on}} = 0.4 \times 10^4$ M$^{-1}$ s$^{-1}$) (Table 1). Moreover, the dissociation rate constant for the DNA containing the \textit{phaP} promoter region ($k_{\text{off}} = 1.7 \pm 0.4 \times 10^{-3}$ s$^{-1}$) was not significantly different from the dissociation rate constant for the DNA containing the \textit{phaR} promoter region ($k_{\text{off}} = 0.9 \times 10^{-3}$ s$^{-1}$) or that of the control DNA ($k_{\text{off}} = 0.7 \times 10^{-3}$ s$^{-1}$). These parameters indicate that PhaR had higher affinity for the \textit{phaP} promoter region than for the \textit{phaR} promoter region. The larger $k_{\text{on}}$ value for the DNA with the \textit{phaP} promoter region must have been due to the length of the recognition sequence for PhaR in the target DNA region. A 32-bp region TGC-rich sequence is recognized by PhaR in the

**Figure 4** Binding behavior of PhaR to am-P(3HB) thin films. (A) Typical time courses of the frequency changes of am-P(3HB) coated on a QCM oscillator, in response to the addition of PhaR. (B) Saturation binding of PhaR to P(3HB). The curve was fitted with a sigmoid curve. [P(3HB)] = 200 $\mu$g cm$^{-2}$ on a QCM, in 10 mM HEPE buffer solution (pH 7.4), 150 mM NaCl, and 0.01% Tween 20 at 25°C. (C) Binding behavior of PhaR to P(3HB) in response to change in the PhaR concentration. The arrow indicates the time of enzyme injection. (D) Linear reciprocal plots of the relaxation rate ($\tau^{-1}$) against PhaR concentrations according to Eq. (4) in the text.
DNA and to am-P(3HB) showed similar binding behaviors of PhaR to P(3HB) molecules. Also, one of the factors responsible for the dissociation of PhaR from DNA is the high affinity of PhaR to P(3HB). The binding of PhaR to DNA and to am-P(3HB) showed similar $k_{on}$ values, suggesting that a concentration-dependent effect caused the expression of phaP with dissociation of PhaR from the phaP promoter region. The insights of the regulation mechanism concerning PhaR in PHA synthesis have the potential to improve the applications of PHA in white and red biotechnology.
