Compiled March 31, 2022

We describe an optical bench in which we lock the relative frequencies or phases of a set of three lasers in order to use them in a cold atoms interferometry experiment. As a new feature, the same two lasers serve alternately to cool atoms and to realize the atomic interferometer. This requires a fast change of the optical frequencies over a few GHz. The number of required independent laser sources is then only 3, which enables the construction of the whole laser system on a single transportable optical bench. Recent results obtained with this optical setup are also presented. © 2022 Optical Society of America

Within the last decades, atom interferometers have developed into a highly competitive tool for precision measurements.\textsuperscript{1} Atomic fountains used as atomic clocks are the best realization of the time unit.\textsuperscript{2} Atom interferometry also promises sensors to be highly sensitive to inertial forces.\textsuperscript{3–6} The use of stimulated Raman transitions to manipulate the atomic wave packet has proven to be an efficient way to obtain high accuracy devices.\textsuperscript{5, 6}

In this letter, we describe a robust, compact and versatile laser system for atom interferometers using alkali atoms. Such experiments basically need two different optical frequencies, whose difference remains close to the hyperfine transition frequency. When they are tuned close to the D2 transitions, they are used to cool and repump the atoms in a magneto-optical trap (MOT). When far detuned, and phase locked, they are used to induce stimulated Raman transitions for the interferometer.\textsuperscript{7} Since lasers are not used simultaneously for trapping and Raman transitions, we have implemented a technique to use the same two lasers for both functions on our gravimeter.\textsuperscript{8} It allowed us to build the whole laser setup on a 60 $\times$ 90 cm$^2$ optical bench.

Our laser setup is shown in figure\textsuperscript{1}. A first laser L1 is locked on an atomic transition, using FM-spectroscopy\textsuperscript{9} on a saturated absorption signal. This laser constitutes an optical frequency reference and is used in our experiment to detect or push the atoms. A second laser L2 is alternately used as repumper or as master Raman laser. Part of the outputs of L1 and L2 are superimposed on a fast photodetector (PD$_{12}$) (Hamamatsu G4176) and the frequency of the beat note is servo locked by using a frequency to voltage converter. A third laser L3 is used alternately as cooling or as slave Raman laser. The frequency difference between L2 and L3 is measured with a second optical beat note on PD$_{23}$. Finally, both L2 and L3 beams are superimposed and directed through an acousto-optical modulator either to a magneto-optical trap or to an atomic interferometer.

Both frequency locks of L2 and L3 use the same scheme which is shown in figure\textsuperscript{4}. The optical beat note issued from the photodetector is mixed with a reference oscillator, down to an intermediate frequency (IF). For the L2 lock this reference is a tunable oscillator (YIG). Whereas for L3 we use a fixed 7 GHz frequency obtained by the multiplication of a low phase noise 100 MHz quartz oscillator. The IF signal is then sent into a digital frequency divider in order to fit into the working frequency range (0-1 MHz) of a frequency to voltage converter (FVC) (AD650). A computer controlled offset voltage $V_{Set}$ is subtracted from the output voltage of the FVC. The obtained error signal is integrated once and added to the laser diode current. This correction signal is integrated again and added to the piezoelectric (PZT) voltage which controls the cavity length. To change the laser frequency, one can change $V_{Set}$ for fine tuning or the YIG frequency for larger frequency changes. In addition, a computer controlled correction current $I_C$ and a correction voltage $V_C$, are added to the current and PZT drivers to help the lock while changing the laser frequency.

For the phase lock of L3 a second path is imple-
The optical beat note is mixed with a reference oscillator to an intermediate frequency (IF). The IF is converted to a voltage signal and another voltage $V_{\text{Set}}$ is subtracted to obtain the error signal of the lock. It is integrated and then sent to the current driver. Pre-determined corrections $I_C$ and $V_C$ are added to the diode current and to the PZT voltage during the sweep. (Dotted line) Phase lock scheme added to L3. The IF is compared to a Local Oscillator (LO) in a digital phase and frequency detector (DPFD) delivering the phase error signal. Two switches select which loop is closed.

Our interferometer is an atomic gravimeter which measures the acceleration of freely falling $^{87}\text{Rb}$ atoms. Its sensitivity is given by: $\Delta \Phi = k_{ef} g T^2$, where $\Delta \Phi$ is the interferometric phase, $k_{ef}$ is the effective wave vector of the Raman transition, $g$ is the Earth’s gravity and $T$ is the time between the interferometer’s Raman pulses.

This frequency locking system is versatile and enables to control dynamically the frequency of the two lasers, over the whole experimental sequence. It is first possible to frequency lock the lasers to the frequencies required to cool $^{87}\text{Rb}$ atoms in a MOT. Dividing the total available laser power between a 2D-MOT$^{11}$ and a 3D-MOT, loading rates of $3 \times 10^8$ atoms.s$^{-1}$ are obtained. Then we turn the magnetic field off and further cool the atoms with $\sigma^+ - \sigma^-$ molasses down to a temperature of 2.5 $\mu$K.

Once the atoms have been released from the molasses, a frequency ramp is applied on the YIG oscillator. This ramp induces a detuning $\Delta$ of up to 2 GHz on both L2 and L3 to get the Raman laser frequencies. We also add a ramp on the PZT voltages $V_C$ to induce a 2 GHz sweep so that the laser frequencies stay inside the locking range. Since the PZT mode-hop free tuning range is close to $\pm$ 0.6 GHz, it is necessary to change the current setting point of the laser during the sweep. Thus we apply ramps on the currents $I_C$ so that the laser frequencies remain in the middle of the free tuning range. When the servo loop is closed, the lasers stay locked during the whole sequence.

In figure 3 is shown the response of the servo system to a frequency ramp of 2 GHz in 2 ms, in open and closed loop configurations. The black curve corresponds to the error signal of L2 in open loop operation. The laser frequency remains within 100 MHz from the locking point during the whole 2 GHz ramp. The voltage ramp does not compensate exactly the sweep because of thermal effects due to the change in the laser current. When the servo loop is closed, the remaining frequency deviation is compensated for. The gray curve shows the residual frequency error of L2 during the sweep, and reveals residual damped oscillations of the PZT.

the cycle. This enables to realize first a velocity selective Raman pulse (∼35 µs), with a detuning of 2 GHz which reduces the spontaneous emission. Then the detuning is swept back to 1 GHz for the interferometer itself, to achieve a better transfer efficiency.

Finally, the phased-locked Raman lasers are used to realize the interferometer. Due to the Doppler effect, the Raman detuning has to be chirped to compensate for the increasing vertical velocity of the atomic cloud. This chirp, obtained by sweeping the DDS frequency, induces an additional phase shift. The total interferometric phase is then given by: $\Delta \Phi = (k_{\text{eff}}g - a)T^2$. Figure 4 displays the interferometric fringes obtained by scanning the chirp rate. In this experiment, $T$ is 40 ms and the sensitivity is already of $4 \times 10^{-8} \text{ g Hz}^{-1/2}$, limited by residual vibrations of the apparatus.

To conclude, this locking technique allowed us to build with only three lasers an optical bench providing the required frequencies to cool $^{87}$Rb atoms in a 3D-MOT and to realize an atomic interferometer with far detuned Raman lasers. Our laser setup is robust and versatile since the lasers routinely stay locked for days and we can change the detuning of the Raman transitions at will. Our goal for the gravimeter experiment is to reach an accuracy of $10^{-9}$ g and a sensitivity of a few $10^{-9}$ g Hz$^{-1/2}$. Thanks to its compactness, the gravimeter will be transportable to compare it with other absolute gravimeters. It will also be moved close to the LNE watt balance experiment, which aims at measuring the Planck’s constant and redefining the kilogram. The authors P. C. and J. L. G. thank DGA for supporting this work. The author K. T. T. thanks also the “Fondation Danoise” for its support.
