We examine a novel type of disorder in quantum antiferromagnets. Our model consists of localized spins with antiferromagnetic exchanges on a bipartite quasiperiodic structure, which is geometrically disordered in such a way that no frustration is introduced. In the limit of zero disorder, the structure is the perfect Penrose rhombus tiling. This tiling is progressively disordered by augmenting the number of random “phason flips” or local tile-reshuffling operations. The ground state remains Néel ordered, and we have studied its properties as a function of increasing disorder using linear spin wave theory and quantum Monte Carlo. We find that the ground state energy decreases, indicating enhanced quantum fluctuations with increasing disorder. The magnon spectrum is progressively smoothed, and the effective spin wave velocity of low energy magnons increases with disorder. For large disorder, the ground state energy as well as the average staggered magnetization tend towards limiting values characteristic of this type of randomized tilings.

This paper discusses the effects of a novel type of geometric disorder on the ground state of Heisenberg antiferromagnets. The clean system is a perfectly deterministic quasiperiodic two-dimensional tiling, and the type of disorder we consider is geometric, involving a discrete shift of a randomly selected subset of sites. These phason flips are operations that correspond to reorganizing the structure locally, in the vicinity of the flipped site. This type of disorder is strongly constrained, as one does not modify the basic building blocks of the structure, but only the way they are connected. For many quasicrystalline alloys, samples of good quality are believed to possess long range order, with some thermally induced phonon and phason disorder present at finite temperatures [1]. However, one can also consider essentially random quasiperiodic structures, which could be preferred for entropic reasons [2].

Quenched phason disorder has been considered previously in other contexts, in particular concerning electronic properties, and the possibility of Anderson localization in such systems was discussed. Benza et al. [3] considered quantum diffusion in a two dimensional randomized tiling, and found that the typical value of the diffusion exponent was larger for the disordered system compared to the pure case. This means that quasicrystals show delocalization-like effects from disorder rather than the opposite, weak localization due to disorder, observed in periodic systems. Piechon and Jagannathan came to the same conclusion by analyzing the statistics of the energy levels in phason disordered tilings (see e.g. Refs. [4, 5, 6] for reviews). Schwabe et al. [7] analyzed the effect of phason flips on the electronic levels and wavefunctions, showing that they lead to a smoothing of the density of states, as well as of the fluctuations of the conductance. Finally, the effects of randomness on the phonon spectrum has been considered in two dimensional quasiperiodic tilings (see e.g. Ref. [8]).

The study of the Heisenberg model on a quasiperiodic tiling is motivated by experimental findings of antiferromagnetic correlations in quasiperiodic ZnMgR alloys (R: rare earth) [9]. In theoretical models considered thus far [10, 11, 12, 13, 14] bipartite tilings are considered, with all sites occupied by spins, and their exchanges restricted to adjacent lattice sites, such that no frustration arises. Furthermore, these studies did not take into account the effects of disorder, which is almost certainly also present in the experimentally studied alloys. Here, we focus on the effects that arise in quasiperiodic magnets in the presence of phason disorder, which is found

FIG. 1: Illustration of a perfect (upper panel) and a phason disordered Penrose tiling (lower panel).
to lead to enhanced quantum fluctuations, as indicated by the lowering of the ground state energy along with a reduction of the staggered magnetization with increasing disorder.

Fig. 1 shows a portion of a perfect (deterministic) Penrose tiling and a typical example of a phason disordered tiling. We consider in the following the antiferromagnetic spin-1/2 Heisenberg model with Hamiltonian $H = J \sum_{i,j} S_i \cdot S_j$ for spins $S_i$ located on all vertices of such tilings. Nearest-neighbor exchanges are antiferromagnetic $J > 0$, and act between pairs of sites that are linked by an edge. Despite the fact that all couplings are equal, the ground state is spatially inhomogeneous contrarily to e.g. the square lattice antiferromagnet, where the staggered magnetization is uniform. The local staggered magnetizations vary as a function of the local environment, and the ground state takes a complex, hierarchically organized structure \cite{10, 11, 12, 13, 14}. The disorder considered here is purely geometric, i.e. the coupling $J$ along bonds remains fixed at a constant value.

Using linear spin wave theory (LSWT) and quantum Monte Carlo (QMC) calculations, we consider periodic approximants of the Penrose tiling \cite{13, 14}. These are finite samples of $N$ spins, satisfying periodic boundary conditions. Perfect tilings are obtained by the cut-and-project method (see e.g. \cite{14}) after which they are disordered, by the following method: A phason flip is a process by which a 3-fold site hops to a new allowed position (in terms of the tile configurations). The old site disappears, by which a 3-fold site hops to a new allowed position (in terms of the tile configurations). The old site disappears, and a new 3-fold site appears on the other sublattice (Fig. 2). In our phason generating procedure, we randomly select a three-fold site. If $r_0$ and $r_j$ ($j = 1, 2, 3$) denote the position vectors of the central site and its three neighbors, the new position of the site is given by $r'_0 = \sum_{j=1}^{3} (r_j - r_0)$ (Fig. 2). Three new bonds appear linking the new site to the sites at the positions $r'_j$ ($j = 1, 2, 3$). The coordination numbers of all of the seven sites involved are updated, and the whole procedure is repeated, with the constraint that there be an equal number of flipped sites on the $A$ and the $B$ sublattice, so as to preserve the condition $N_A = N_B$, where $N_A$ ($N_B$) denotes the number of sites of the $A$ ($B$) sublattice.

For a given total number of phason flips $N_{ph}$, the degree of disorder $\Delta$ is defined as the average overlap distance between the perfect sample and the disordered samples. The overlap for a given sample is defined by $N_{ph}^{-1} \sum_{i=1}^{N_{ph}} \eta_i$, where $\eta_i$ is 1 or 0, depending on whether site $i$ is shifted or not with respect to the perfect tiling. The whole procedure is then repeated for approximants of system sizes $N = 246, 644, 1686$ and 4414 in LSWT and 246, 644 and 1686 in QMC. Averaging is carried out over a large number of samples: 100 samples for $N = 246, 644, 1686$ and 10 samples for $N = 4414$ in LSWT and 40 samples for $N = 246$ and 20 samples for $N = 644, 1686$ in the QMC. This method of disordering does not change the overall number of rhombi of each kind, and generates samples of fixed phason strain \cite{15}. Due to the fact that we obtain a defected structure (a periodic approximant, which is only locally equivalent to the infinite quasiperiodic tiling) there is an upper limit to the number of phason flips we are able to introduce in the tilings. Unacceptable configurations are observed to appear after a number of flips larger than about 1.3$N$, corresponding to the number of steps after which the periodic boundary conditions are felt by the system.

After the randomized samples are obtained, LSWT calculations are performed as described in \cite{12, 14}. Spin
operators are transformed using the Holstein-Primakoff transformation to bosonic operators $a_i$, $b_j$ ($i,j = 1, ..., N/2$), corresponding the $A$ and $B$ sublattices respectively. The linearized Hamiltonian in the boson operators is then diagonalized numerically. Once the eigenvalues of the disorder strength $\Delta$ from LSWT on the $N = 11,144$ sites system.

We now describe our results on the effect of phason disorder. First, we consider the average ground state energy per site $E_0/N$, shown as a function of disorder in Fig. for the $N = 4414$ sites system. The values have been normalized with respect to the value obtained for the clean system. Also shown is a fit to an exponential decay towards a limiting value in the strong disorder case, of the form $E_0/N = e_{\text{dis}} + (e_{\text{per}f} - e_{\text{dis}})e^{-a\Delta}$, with $a = 11.16$, $e_{\text{dis}} = -0.6500$ and $e_{\text{per}f} = -0.6429$. The asymptotic value of the ground state energy $e_{\text{dis}}$ represents the average value of the ground state energy of maximally randomized Penrose approximants, which lies below the ground state energy of the perfect system. This indicates that the introduction of phasons tends to enhance quantum fluctuations in the tilings, as compared to the clean case. The inset of Fig. shows the ground state energy per site as a function of disorder, obtained from LSWT and QMC simulations, normalized with respect to the value obtained for the clean system. The results obtained from LSWT and QMC are found to be in good agreement. This also shows the applicability of the linear spin wave approximations to this randomized system.

Next, we consider the density of states, defined via $\rho(E) = \sum_\mu \delta(E - \omega_\mu)$, and shown in Fig. We find that the dominant effect of phason disorder on the density of states is to progressively smoothen fluctuations and fill in gaps, as in the electronic case. The low energy tail is quadratic, and can be fitted to obtain the averaged low-energy spin wave velocity $\bar{c}$, that increases with $\Delta$ as shown in the inset of Fig. This indicates that spin wave propagation is facilitated by the phason disorder, in analogy with the problem of quantum diffusion of electrons in the tight binding model in quasiperiodic tilings. In addition, the localized states at $E = 3$ disappear progressively. These states arise on closed loops of 3-fold sites. They are hence destroyed when a phason flip occurs on one of the participating sites.

Finally, we turn to discuss the evolution of the staggered magnetization upon introducing phason disorder. Fig. shows the spatial average of the staggered magnetization (i.e. after averaging over all of the sites) as a function of disorder, normalized with respect to the value obtained for the clean system. The curve shows a clear decrease in the global staggered magnetization with increasing disorder. As for the ground state energy curve, the decrease eventually levels off. It is also interesting to analyze the evolution of the full distribution of the staggered magnetizations with increasing phason disorder. In the perfect tiling, this distribution has several peaks, each of which corresponds to a distinct coordination number. In the disordered tilings, the differences between the coordination number is smoothed out. As Fig. shows,
FIG. 6: Evolution of the distribution in the local staggered magnetization with the disorder strength, as obtained within LSWT on the 4414 sites system.

FIG. 7: (Color online) Color representation of the local staggered magnetizations in a perfect tiling (left) and a disordered tiling (right) showing sites of magnetizations ranging from high (blue) to low (red) values.

the distribution becomes smoother, as the disorder is increased. In addition, the average value shifts to lower values. The smoothing occurs due to a larger number of local environments created by the phason flips, and due to the loss of self similarity on larger length scales. 

Fig. 7 shows that the distribution is more homogeneous in the disordered tiling, which furthermore lacks the hierarchical features of the perfect tiling. The redder appearance of the right figure also illustrates the already noted fact, that globally the staggered magnetization is lower in the disordered system.

In conclusion, we analyzed the effects of a new type of geometrical disorder on the magnetic properties of quasiperiodic antiferromagnets. Concerning the low energy modes, magnons propagate with a slightly higher velocity in the disordered tiling as compared to the perfect quasiperiodic tiling. The density of states is smoothed. Degenerate states localized on closed loops disappear with increasing disorder. Eigenmodes tend to become more delocalized as compared to the perfect tiling. These effects have their analogy in phonon models, as well as in the tight binding model for electrons in quasiperiodic tilings. In the magnetic problem our results also indicate that the effect of disorder is to reduce the strong coherent backscattering of the magnon wavefunctions due to a perfect quasiperiodic potential and to favor a more diffusive dynamics. Upon increasing phason disorder in the antiferromagnetic model, the ground state progressively loses its self-similar features, and tends towards a more homogeneous distribution of staggered moments. The global average of the staggered magnetization decreases, as does the ground state energy, signaling increased quantum spin fluctuations. Both quantities tend towards a limiting value for this class of disordered tilings. Such two dimensional quantum antiferromagnets may be experimentally realizable in the near future, as there has been considerable progress recently with depositing atoms on quasiperiodic surfaces, which serve as templates. A monolayer of Pb atoms having quasiperiodic symmetry has been obtained [17]. To study quantum magnetism one needs to obtain such a surface layer using low spin atoms. In addition, one needs the interactions to be predominantly short range and antiferromagnetic, and this could be realized via a superexchange mechanism, as in the cuprate layers of high $T_c$ compounds, in which oxygen atoms mediate the exchange between the $S = 1/2$ copper spins.
