(Dated: November 3, 2018)

Recent BaBar data on the pion transition form factor, whose \( Q^2 \) dependence is much steeper than predicted by asymptotic Quantum Chromodynamics (QCD), have caused a renewed interest in its theoretical description. We present here a formalism based on a model independent low energy description and a high energy description based on QCD, which match at a scale \( Q_0 \). The high energy description incorporates a flat pion distribution amplitude, \( \phi(x) = 1 \), at the matching scale \( Q_0 \) and QCD evolution from \( Q_0 \) to \( Q > Q_0 \). The flat pion distribution is connected, through soft pion theorems and chiral symmetry, to the pion valance parton distribution at the same low scale \( Q_0 \). The procedure leads to a good description of the data, and incorporating additional twist three effects, to an excellent description of the data.

I. INTRODUCTION

The implications of recent data by the BaBar Collaboration [1] on the transition form factor \( \gamma^*\gamma \to \pi^0 \), in our understanding of the structure of the pion are being widely discussed [2–6]. These results have cast doubts on our understanding on the behavior, as a function of the light-cone momentum fraction \( x \), of the pion distribution amplitude (\( \pi DA \)) \( \phi(x) \) [7, 8]. Some investigations have produced scenarios where the pion \( \pi DA \) is flat, i.e. a constant value for all \( x \) [2, 3], and are in good agreement with the data for the form factor. These scenarios are compatible with QCD sum rules [3] and lattice QCD [9, 10] calculations which provide values for the second moment of the \( \pi DA \) which are large compared with the asymptotic value \( 6x(1-x) \) [7, 1]. Model calculations, Nambu-Jona-Lasinio (NJL) [11–13] and the "spectral" quark model [15] give a constant pion distribution amplitude, \( \phi(x) = 1 \). The pion transition form factor calculated in these models, however, overshoots the data [10].

In here we present a formalism to calculate the pion transition form factor (\( \pi TFF \)) which provides an excellent description in the whole range of experimental data. The formalism consists of three ingredients: i) a low energy description of the \( \pi TFF \); ii) a high energy description of the \( \pi TFF \); iii) a matching condition between the two descriptions at a scale \( Q_0 \) characterizing the separation between the two regimes. For the low energy description we take a parametrization of the low energy data to avoid model dependence at \( Q_0 \). The high energy description of the \( \pi TFF \), defined by the pion Distribution Amplitude (\( \pi DA \)), contains Quantum Chromodynamic (QCD) evolution from \( Q_0 \) to any higher \( Q \), the recently introduced mass cut-off procedure [2], and ultimately additional higher twist effects. The relation between the leading twist \( (\pi DA) \) and the pion Parton Distribution \( (\pi PD) \) allows us to use a scheme for the determination of \( Q_0 \) that has proven successful to describe parton distributions of mesons and baryons [17–23]. The scheme consists in evolving the second moments of the parton distributions from a scale where they are experimentally known to a scale \( Q_0 \) where they coincide with those determined by a low energy description. Once \( Q_0 \) is known, higher \( Q \) results for any other observable are obtained by evolving the low energy description of the corresponding observable from \( Q_0 \) to the required scale \( Q \). Our analysis will systematically explore the region of validity of the scheme and find implications of new physics in the intermediate energy region.

In section II we define the \( \pi TFF \) both for low and high energies and establish the matching condition at the hadronic scale \( Q_0 \). The matching condition of section II allows to determine the mass parameter of the formalism once the hadronic scale is known. Section III is devoted to establish a relation between the \( \pi DA \) and the \( \pi PD \). This relation allows to characterize a unique matching scale \( Q_0 \). Section IV is dedicated to analyze the stability of the parameters and the description of the data. We find reasonable agreement with the experimental data for \( Q^2 \) below 15 GeV\(^2 \) with parameters whose values are to be expected from physical arguments. Two matching scales are investigated in the analysis. We realize that none of them is able to reproduce accurately the slope of the data in

In this expression, the $Q$ in terms of the Gegenbauer polynomials \[28, 29\], introduce a cutoff mass $M$ the divergences in the integrand of Eq. (1) we follow the proposal of Radyushkin in section II.B of ref. \[2\], and we

$$Q \pi_{DA}$$

of one of the photons it has been measured by the CELLO \[26\], by the CLEO \[27\] and recently by the BaBaR \[1\] collaboration. The last results are in disagreement with previous theoretical expectations.

In section V we incorporate in a phenomenological way additional twist three effects. They lead to a modification of the matching condition. Their overall effect is small at high $Q$ but they are important in reproducing the slope in the intermediate region. In this way we are able to get an excellent agreement with the data.

In section VI we draw some conclusions. Finally, in the Appendix we present a model calculation which overshoots the data and therefore signals the importance of evolution in the description of the experiment. Moreover, it also serves to understand the order of magnitude of some of the parameters used in our approach.

II. THE PION TRANSITION FORM FACTOR.

The form factor $F_{\gamma \gamma \pi}$ relating two photons (real or virtual) to the pion is a very important object of study in exclusive processes in QCD. In particular it has been used by comparing perturbative QCD predictions with experimental data to obtain information about the shape of the $\pi DA$\[7, 24, 25\]. Experimentally for small virtuality of one of the photons it has been measured by the CELLO \[26\], by the CLEO \[27\] and recently by the BaBaR \[1\] collaboration. The last results are in disagreement with previous theoretical expectations.

In lowest order of perturbative QCD, the transition form factor for the process $\pi^0 \to \gamma \gamma^*$ is given by

$$Q^2 F(Q^2) = \frac{\sqrt{2} f_\pi}{3} \int_0^1 \frac{dx}{x} \phi_\pi(x, Q^2).$$  \(1\)

where $Q^2 = -q^2$, $q_\mu$ is the momentum of the virtual photon, $\phi_\pi(x, Q^2)$ is $\pi DA$ at the $Q^2$ scale and $f_\pi = 0.131$ GeV.

In this expression, the $Q^2$ dependence appears through the QCD evolution of the $\pi DA$. The $\pi DA$ can be expressed in terms of the Gegenbauer polynomials \[28, 29\],

$$\phi_\pi(x, Q^2) = x(1-x) \sum_{n(even)=0}^\infty a_n C_n^{3/2}(2x - 1) \left( \log \frac{Q^2}{\Lambda_{QCD}^2} \right)^{-\gamma_n},$$  \(2\)

where $\gamma_n$ are the anomalous dimensions

$$\gamma_n = \frac{C_F}{\beta} \left( 1 + 4 \sum_{k=2}^{n+1} \frac{1}{k} - \frac{2}{(n+1)(n+2)} \right),$$  \(3\)

$\beta = \frac{11N_c}{3} - \frac{2N_f}{3}$ is the beta function to lowest order and $C_F = \frac{N_c^2 - 1}{2N_c}$. Assuming that the $a_n$ coefficients are known, Eq. (1) gives the $\pi TFF$ for any value of $Q$ high enough compared with $\Lambda_{QCD}$. The $a_n$ coefficients are obtained if we know the $\pi DA$, $\phi_\pi(x, Q_0^2)$, at some momentum $Q_0$, using the orthogonality relations of the Gegenbauer polynomials

$$a_n \left( \log \frac{Q_0^2}{\Lambda_{QCD}^2} \right)^{-\gamma_n} = 4 \frac{2n + 3}{(n+1)(n+2)} \int_0^1 dx C_n^{3/2}(2x - 1) \phi_\pi(x, Q_0^2)$$  \(4\)

In order to prevent divergences in the integrand of Eq. (1) it has been assumed that $\phi_\pi(x)$ vanishes for $x = 0$. There are no fundamental reasons for this restriction, moreover, several chiral models predict for massless pions $\phi_\pi(x) = 1$ \[11, 14\]. We use this model prediction as input at $Q_0$ in Eq (1) and we obtain for the expansion of the $\pi DA$

$$\phi_\pi(x, Q^2) = 4x(1-x) \sum_{n(even)=0}^\infty \frac{2n + 3}{(n+1)(n+2)} C_n^{3/2}(2x - 1) \left( \log \frac{Q^2}{\Lambda_{QCD}^2} \right)^{-\gamma_n}. \tag{5}$$

This expression has the right asymptotic behavior, $\lim_{Q \to \infty} \phi_\pi(x, Q) = 6x(1-x)$. Nevertheless, despite its appearance, the $\pi DA$ defined in Eq. (5) has the properties $\lim_{x \to 0+} \phi_\pi(x, Q_0) = \lim_{x \to 1-} \phi_\pi(x, Q_0) = 1$. In order to cure the divergences in the integrand of Eq. (1) we follow the proposal of Radyushkin in section II.B of ref. \[2\], and we introduce a cutoff mass $M$ in the above definition of the $\pi TFF$, in terms of the $\pi DA$,

$$Q^2 F(Q^2) = \frac{\sqrt{2} f_\pi}{3} \int_0^1 \frac{dx}{x + \frac{M^2}{Q^2}} \phi_\pi(x, Q^2).$$  \(6\)
FIG. 1: Calculation of the transition form factor via the triangle diagram.

We will discuss later the determination of the $M$.

At low $Q^2$ we can parametrize the data as

$$F(Q^2) = F(0) \left[ 1 - a \frac{Q^2}{m_{\pi^0}^2} + ... \right]$$  \hfill (7)

with $F(0) = 0.273(10)$ GeV$^{-1}$ and $a = 0.032(4)$, constants which have been obtained from the experimental study of $\pi^0 \rightarrow \gamma e^+ e^-$. The $\pi TFF$ at these low values of $Q^2$ can be described by several hadron models. For instance, the parametrization can be well understood studying the triangle diagram (see Fig. 1). This calculation is straightforward (see appendix) leading, in the case of massless pions, to

$$F(0) = \sqrt{2} \pi^3 \int_0^1 \frac{dx}{x + \frac{M^2}{Q_0^2}} = \sqrt{2} \pi^3 \ln \frac{Q_0^2 + M^2}{M^2},$$

$$Q_0^2 F(Q_0^2) = \frac{\sqrt{2} f_\pi}{3} \ln \frac{Q_0^2 + M^2}{M^2},$$  \hfill (9)

to the value given by the monopole parametrization Eq. (8),

$$\sqrt{2} f_\pi \ln \frac{Q_0^2 + M^2}{M^2} = Q_0^2 F^{LE}(Q_0^2) = F(0) \frac{Q_0^2}{1 + a \frac{Q_0^2}{m_{\pi^0}^2}}.$$  \hfill (10)

This is the first equation relating the two parameters. We proceed in the next section to find a second relation relation which allows a full determinations of the parameters.
III. THE PION DISTRIBUTION AMPLITUDE AND THE PION PARTON DISTRIBUTION.

In this section we establish a relation between the $\pi DA$ and the pion valence parton distribution ($\pi VPD$) which will be instrumental in the determination of $Q_0$.

The $\pi DA$ is defined by,

$$\delta_{ij} i \sqrt{2} f_\pi \phi_\pi(x) = \int \frac{d\lambda}{2\pi} e^{i\lambda x} \langle 0 \mid \bar{\psi}(0) \gamma^+ \gamma_5 \tau^i \psi(\lambda n) \mid \pi^j(P) \rangle.$$  \hspace{1cm} (11)

In order to introduce a convenient expression for the valence parton distribution let us define the quark distribution $H^{i,j}_{q}(x) = \frac{1}{2} \int \frac{d\lambda}{2\pi} e^{i\lambda x} \langle \pi^j(P) \mid \bar{\psi}(0) \gamma^+ \gamma_5 \tau^i \psi(\lambda n) \mid \pi^j(P) \rangle$. Therefore $H^{i,j}_{q}(x) = H_1^{i,j}(x)$.

Substituting Eq. (18) in Eq. (16) we obtain

$$H^{i,j}_{q}(x) = \frac{1}{2} \int \frac{d\lambda}{2\pi} e^{i\lambda x} \langle \pi^j(P) \mid \bar{\psi}(0) \gamma^+ \gamma_5 \tau^i \psi(\lambda n) \mid \pi^j(P) \rangle = \frac{1}{2} \left( \delta_{ij} H^{I=0}(x) + i \epsilon_{i3j} \alpha H^{I=1}(x) \right)$$ \hspace{1cm} (12)

with $\alpha = \pm 1$ for $q = u, d$ and $H^{I=0,1}(x)$ represent the isospin decompositions. The quark distribution is only non-vanishing in the interval $-1 \leq x \leq 1$. This quark distribution is related with the standard $q(x)$ and $\bar{q}(x)$ distributions, by

$$H^{\pi}_{q}(x) = q(x) \theta(x) - \bar{q}(-x) \theta(-x),$$ \hspace{1cm} (13)

with

$$H^{\pi}_{q} = H^{\pi}_{q} = \frac{1}{2} \left( H^{I=0}(x) + H^{I=1}(x) \right).$$ \hspace{1cm} (14)

$$H^{\pi}_{q} = H^{\pi}_{q} = \frac{1}{2} \left( H^{I=0}(x) - H^{I=1}(x) \right).$$ \hspace{1cm} (15)

The pion valence parton distribution ($\pi VPD$) is defined as $H^{\pi}_{q}(x) = H^{\pi}_{q}(x) + H^{\pi}_{q}(-x)$. Using charge conjugation, one can prove that the isoscalar and isovector parton quark distribution, $H^{I=0,1}(x)$, are respectively odd and even functions of $x$. Therefore

$$H^{i,j}_{Vq}(x) = \frac{1}{2} \int \frac{d\lambda}{2\pi} e^{i\lambda x} \langle \pi^j(P) \mid \bar{\psi}(0) \gamma^+ \gamma_5 \tau^i \psi(\lambda n) \mid \pi^j(P) \rangle = \frac{1}{2} \left( \delta_{ij} H^{I=0}(x) + i \epsilon_{i3j} \alpha H^{I=1}(x) \right).$$ \hspace{1cm} (16)

In terms of the standard $q$ and $\bar{q}$ distributions we have

$$H^{i,j}_{Vq}(x) = \frac{1}{2} \alpha \epsilon_{i3j} \left[ q_{V}(x) \theta(x) + q_{V}(-x) \theta(-x) \right].$$ \hspace{1cm} (17)

Soft pion theorems have been used to relate the double pion distribution amplitude to the $\pi DA$. Using the same arguments, it is easy to connect the matrix elements of the preceding definitions,

$$\lim_{P \to 0} \langle \pi^i(P) \mid \bar{\psi}_{f}(0) \gamma^+ \gamma_5 \tau^i \psi_{f}(\lambda n) \mid \pi^j(P) \rangle = i \epsilon_{i3j} \sqrt{2} \lim_{P \to 0} \langle 0 \mid \bar{\psi}_{f}(0) \gamma^+ \gamma_5 \tau^i \psi_{f}(\lambda n) \mid \pi^j(P) \rangle.$$ \hspace{1cm} (18)

and therefore

$$H^{i,j}_{Vq}(x) = \frac{1}{2} (\alpha) \epsilon_{i3j} \left[ \phi_{\pi}(x) \theta(x) + \phi_{\pi}(-x) \theta(-x) \right].$$ \hspace{1cm} (19)

Substituting Eq. (18) in Eq. (16) we obtain

$$\phi_{\pi}(x) = q_{V}(x),$$ \hspace{1cm} (20)

a relation which is important for our scheme because it provides a universal determination of the hadronic scale $Q_0$.

The previous result, Eq. (20), is confirmed by chiral models for the pion, like the NJL model or the spectral quark model. In fact, these local chiral quark models give, in the chiral limit, $\phi_{\pi}(x) = q(x) = 1$. Using the results obtained in the NJL model for the $\pi DA$ (see [13]) and the $\pi PD$ (see [32]) we obtain

$$\phi_{\pi}(x) = 1 + \mathcal{O}(m_q^2), \quad q_{V}(x) = \frac{g_{\pi gg} f_{\pi}}{\sqrt{2} m_q} + \mathcal{O}(m_q^2) = 1 + \mathcal{O}(m_q^2).$$ \hspace{1cm} (21)
where in the last relation \( m_q \) is the constituent quark mass, \( g_{\pi qq} \) is the pion quark coupling constant and the last step follows from the Goldberger-Treiman relation. This result for \( q_V(x) \) arises naturally from the physical meaning of the \( \pi VPD \). The flatness of the distribution implies that the probability of finding a quark of any relative momentum fraction \( x \) is the same. This is so because in the chiral limit quarks and pions are massless and therefore there is no mass scale to which the momentum distribution can attach. The appearance of flat distributions is a fundamental consequence of soft pion theorems and the chiral limit, not a peculiarity of some models.

Since the origin of the flat distribution is related to soft pion theorems and the chiral limit, this behavior will change as we move towards higher energy. Starting from \( Q_0 \), the momentum scale in which the flat distributions are a good approximation, \( \phi(x, Q_0) = q_V(x, Q_0) = 1 \), we apply the evolution equations in order to obtain these distributions at higher \( Q \) values. The \( \pi VPD \), \( q_V(x, Q) \) evolves through the DGLAP equation, and it concentrates close to the \( x \sim 0 \) region for very high values of \( Q \). The \( \pi DA \) evolves through the ERBL equation and, therefore, for high \( Q \) values we obtain the asymptotic result \( \phi(x, Q) \sim 6x(1-x) \). In conclusion, QCD evolution obscures the relation between these two distributions, which become distinct from one another. It follows from the above discussion that it is unreasonable to assume that at relatively low energies \( \phi(x) \) is close to its asymptotic value, whereas the \( \pi VPD \) is far from it.

The evolution of the flat \( \pi VPD \), \( q(x, Q_0) = 1 \), has been previously studied in refs. \cite{17, 21, 23} obtaining a very good description of the experimental data. We sketch here the procedure to fix the value of the matching point, \( Q_0 \). We know that the momentum fraction of each valence quark at \( Q = 2 \text{ GeV} \) is 0.23 \cite{22}. We fit the initial point of the evolution, \( Q_0 \), imposing that the evolved \( \pi VPD \) reproduces this momentum fraction at \( Q = 2 \text{ GeV} \). Obviously, the resulting \( Q_0 \) value will depend on the value of \( \Lambda_{QCD} \). Varying \( \Lambda_{QCD} \) form 0.174 GeV to 0.326 GeV we obtain that \( Q_0 \) changes from 0.290 GeV to 0.470 GeV, in leading order (LO) evolution. A change in \( \Lambda_{QCD} \) implies a change in the initial point \( Q_0 \), but, once we have fitted \( Q_0 \) through the momentum fraction carried by the quarks at \( Q = 2 \text{ GeV} \), the evolved parton distribution is independent of the value of \( \Lambda_{QCD} \) and the quality in the description of the experimental data is preserved.

At this point we must return to Eq. \cite{10} regarding the stability of \( M \). We obtain that \( M \) changes only a few MeV when we vary \( \Lambda_{QCD} \) form 0.174 GeV to 0.326 GeV. The largest incertitude comes from the experimental error in \( a \), obtaining \( M = 0.466 \pm 0.006 \) GeV. We thus obtain a very stable value for \( M \), showing the consistency of the procedure. For the numerical analysis we have chosen \( \Lambda_{QCD} = 0.226 \) GeV, \( Q_0 = 0.355 \) GeV, \( a = 0.32 \) and \( M = 0.466 \) GeV.

IV. DISCUSSION.

Summarizing the ideas developed previously, a model independent scheme of evaluation for the \( \pi TFF \) at high \( Q \) values arises under the following assumptions: i) we consider, on the basis of chiral symmetry and soft pion theorems, that at some point \( Q_0 \) the \( \pi DA \) and the \( \pi VPD \) coincide and have flat behavior \( \phi(x, Q_0) = q_V(x, Q_0) = 1 \); ii) we fix \( Q_0 \) applying QCD evolution to the \( \pi VPD \) from \( Q_0 \) to \( Q = 2 \text{ GeV} \) and impose that each valence quark carries a fraction of the total momentum of the pion of 0.23; iii) for \( Q < Q_0 \) we assume the experimental parametrization of \( F(Q^2) \) given in \cite{23}; and iv) for \( Q > Q_0 \) the \( \pi TFF \) is given by the Eq. \cite{6}, where we fix the \( M \) parameter through the continuity condition Eq. \cite{10}.

In Figs. \cite{2} and \cite{3} we show the \( \pi TFF \) calculated using the evolved \( \pi DA \) as explained above and compare with the data of refs. \cite{1, 26, 27}.

In ref. \cite{21} for the pion, and in refs. \cite{19, 20} for the nucleon, it is shown that including gluons and sea quarks at low energy the preferred starting point for evolution is \( Q_0 \approx 1 \text{ GeV} \). To move \( Q_0 \) up to 1 GeV implies to change the value of \( M \) to 0.500 GeV. Dashed curves in Fig. \cite{2} and \cite{3} reproduces the \( \pi TFF \) calculated with these parameters. The experimental incertitude in \( a \) produces in this case a larger indetermination in the mass, obtaining \( M = 0.500 \pm 0.040 \) GeV. Nevertheless, this error does not affect to the predictive power, as shown in Fig. \cite{2}.

The calculation shows several features which we now discuss. The first effect of this model independent calculation, in comparison with the triangle result, is to cure the asymptotic behavior of the form factor. Model calculations overshoot the experimental data for \( Q^2 \sim 10 - 30 \text{ GeV}^2 \) as is clear from ref. \cite{16} and it is confirmed by our calculation of the triangle diagram (see appendix), where we obtain \( Q^2 F(Q^2) \sim 0.54 \text{ GeV} \) for \( Q^2 \sim 30 \text{ GeV}^2 \). Moreover, the form factor in this model calculation shows a behavior proportional to \( [\log (Q^2/m^2)]^2 \) for high \( Q^2 \). Now, with the procedure defined here, we recover the right asymptotic result \( Q^2 F(Q^2) \rightarrow \sqrt{2} f_x \). What is under discussion at present is not this value, but for which value of \( Q^2 \) the asymptotic behavior is attained and the behaviour of the \( \pi TFF \) in the intermediate energy region.

In Fig. \cite{3} we observe that the calculation with the mass cut-off introduced in ref. \cite{2} adjusts well to the data up to \( Q^2 \sim 15 \text{ GeV}^2 \), when we use as matching point at \( Q_0 = 0.355 \) GeV. However, at that moment most of the new data bend upward while our calculation remains practically flat (see Fig. \cite{2}). The slope of the \( \pi TFF \) in the region
FIG. 2: Calculation of the transition form factor via the $\pi DA$ with $M = 0.466$ GeV, $a = 0.032$ and defining the matching point at $Q_0 = 0.355$ GeV (full-line) compared with the experimental data. The dashed-line corresponds to the same calculation defining the matching point at $Q_0 = 1$ GeV and with $M = 0.500$ GeV. The dotted-line corresponds to the asymptotic limit. The gray region gives the indeterminacy of the results due to the error in $a$, which is only appreciable for the $Q_0 = 1$ GeV case.

FIG. 3: Same as in Fig 2 for the $Q^2$ region under 17 GeV$^2$. 
around 20 GeV$^2$ is not well reproduced. If we assume the higher matching point $Q_0 = 1$ GeV, the calculation still fits relatively well the low energy data up to 5 GeV$^2$, but, contrary to the other, fails in the intermediate region, as we see in Fig 8. In the region around 20 GeV$^2$, this calculation goes through most of the experimental points although the slope of the curve is smaller than the one indicated by the data. The indeterminacy in the predictions related to the experimental error in $a$ is only appreciable when we use $Q_0 = 1$ GeV as matching point. It is represented by the gray region in Fig 2 corresponding the upper limit of the region to $a = 0.028$ and the lower limit of to $a = 0.036$. In both calculations, the $\pi TFF$ tends to the asymptotic limit at very high energy, but in the studied region it is growing very slowly ($Q_0 = 1$ GeV case) or it is practically constant ($Q_0 = 0.355$ GeV case). The value of the mass parameter, around 0.450–0.500 GeV, is reasonable, since it receives contributions not only from de constituent quark mass, but also from the mean value of the transverse momentum.

V. POSSIBLE TWIST THREE EFFECTS IN THE PION TRANSITION FORM FACTOR.

Using $Q_0 = 0.355$ GeV as matching point, the experimental results are well reproduced up to 15 GeV$^2$, but it is difficult to accommodate the higher momentum results. QCD is asymptotically free, and the perturbative approach leading to Eq. (1) must be right for high enough momentum transfer. To correct the high momentum region without touching the low momentum region is not easy, and might require new effects, as the one shown in ref. [4].

On the other hand, using $Q_0 = 1$ GeV as matching point, the high momentum results are well reproduced, but with a too small slope, and the lower momentum data are over estimated. Here we are in a more confortable situation from the point of view of QCD. In order to cure the divergences in the integrand of Eq. (1) we have introduced a cutoff mass $M$ in the definition of the $\pi TFF$ in terms of the $\pi DA$, recall Eq. (6). This procedure incorporates effects of twist three operators at low energy. The set of twist three distribution amplitudes for pions are $\langle 0 | f (0) \bar{c} \gamma_5 t^u (z) | \pi^+ \rangle$, $\langle 0 | f (0) \bar{c} \gamma_5 t^u (z) | \pi^0 \rangle$, and $\langle 0 | f (0) \bar{c} \gamma_5 t^u (z) | \pi^- \rangle$. Some of the effects of these operators are included in the modification proposed by Radyushkin, but there can be additional effects, like the presence of gluons, which are not incorporated in his procedure. These additional effects can be introduced by adding to the lowest order calculation a term proportional to $Q^{-2}$,

$$Q^2 F(Q^2) = \frac{\sqrt{2} f_\pi}{3} \int_0^1 \frac{dx}{x+M^2/Q^2} \phi_\pi(x, Q^2) + C_3 \frac{Q^2}{Q^2}.$$  \hfill (22)

The effect of $C_3$ decreases rapidly with $Q^2$, and therefore we consider $C_3$ constant in $Q^2$. Even though this constant is connected to twist three operators, its QCD evolution is unimportant here.

Following the same ideas developed in Section II we change the matching condition, Eq (10) in order to introduce the effect of the new term:

$$\frac{\sqrt{2} f_\pi}{3} \ln \frac{Q_0^2}{M^2} + C_3 \frac{Q_0^2}{M^2} + \frac{C_3}{1 + a \frac{Q^2}{M^2}}.$$  \hfill (23)

With $Q_0 = 1$ GeV, this equation allows to determine $M$, once we have fixed the value of $C_3$.

We consider three scenarios, which correspond to a contribution from the twist three term to the form factor at $Q_0 = 1$ GeV of 10% ($C_3 = 0.99 \times 10^{-2}$ GeV$^3$), 20% ($C_3 = 1.98 \times 10^{-2}$ GeV$^3$) and 30% ($C_3 = 2.98 \times 10^{-2}$ GeV$^3$). If we fix $C_3 = 1.98 \times 10^{-2}$ GeV$^3$, which implies that this term is responsible for a 20% of the value of the $\pi TFF$ at $Q_0 = 1$ GeV, the experimental error in $a$ produces a variation of $M = 0.620 \pm 0.050$ GeV. To check the stability of the $M$ value in relation to $C_3$, we fix $a = 0.032$ and vary $C_3$ from $C_3 = 0.99 \times 10^{-2}$ GeV$^3$ to $C_3 = 2.98 \times 10^{-2}$ GeV$^3$. This produces a variation of $M$ given by $M = 0.620 \pm 0.070$ GeV. The indeterminacy in $M$ is in all cases of the order of 10%, which is of the same order of the relative error in the experimental determination of $a$. The value of $M$ is sufficiently stable to confirm the consistency of the procedure. For the numerical analysis we have chosen $\Lambda_{QCD} = 0.226$ GeV, $Q_0 = 1$.GeV, $a = 0.032$ and $C_3 = 1.98 \times 10^{-2}$ GeV$^3$ which corresponds to a 20% contribution of twist 3 at $Q_0$. This set of parameters implies $M = 0.620$ GeV.

---

$\footnote{A dimensionless definition of the parameter $C_3$ could be $C_3 = a_3 \left( m_{\pi}^2/a \right) f\pi$, with $a$ the experimental parameter given in Eq. (8).}$

Therefore, $C_3 = 1.98 \times 10^{-2}$ GeV$^3$ corresponds to $a_3 = 0.27$. In the Appendix we give the value for $C_3$ obatined from the triangle diagram.
FIG. 4: Calculation of the transition form factor via the \( \pi DA \) with \( M = 0.620 \text{ GeV}, a = 0.032, C_3 = 1.98 \times 10^{-2} \text{ GeV}^3 \) and defining the matching point at \( Q_0 = 1 \text{ GeV} \) (full-line) compared with the experimental data. The gray region gives the indeterminacy of the results due to the indeterminacy on \( C_3 \).

In Fig. 4 and 5 we show the \( \pi TFF \) calculated using the evolved \( \pi DA \) compared with the data of \([1, 26, 27]\). In Fig 5 we have used the experimental parametrization \([3]\) for \( Q^2 < 1 \text{ GeV}^2 \) (short dashed line). For \( Q^2 > 1 \text{ GeV}^2 \), the full line corresponds our calculation using Eq. (22) together with the evolved \( \pi DA \). The gray region corresponds to the effect due to the different contributions of the \( C_3 \) term: the upper limit corresponds to \( C_3 = 0.99 \times 10^{-2} \text{ GeV}^3 \) (10\% of twist 3 contribution at \( Q^2 = 1 \text{ GeV} \)); the lower limit corresponds to \( C_3 = 2.98 \times 10^{-2} \text{ GeV}^3 \) (30\% of twist 3 contribution at \( Q^2 = 1 \text{ GeV} \)); the dashed curve in Fig. 5 corresponds to the contribution coming from the \( C_3 \) term for our central value, \( C = 1.98 \times 10^{-2} \text{ GeV}^3 \). We observe that its contribution is absolutely negligible for \( Q^2 > 5 \text{ GeV}^2 \). Nevertheless, its influence in the matching point is important for a good description of the low \( Q^2 \) data. Looking at the whole of the Figs. 4 and 5 we observe that we have a good determination of the experimental data in the whole experimental region.

VI. CONCLUSIONS

In the previous sections we have developed a formalism to describe the \( \pi TFF \) on all experimentally accessible range, and hopefully beyond. The formalism is based on a two energy scale description. The formulation in the low energy scale is non perturbative, while that of the high energy scale is fundamentally a QCD based perturbative formulation. The two descriptions are matched at an energy scale \( Q^0 \) hereafter called hadronic scale. This scheme has been applied to described the parton and generalized parton distributions with notable success\([18–20, 33]\). In order to understand the finesse of the BaBaR data we have forced us to introduce additional ingredients to this scheme which we next summarize.

We have taken for the low energy description of the \( \pi TFF \) a parameterized description of the data. This has been done to avoid model dependence in a region \( (Q \sim 1 \text{ GeV}) \), where models might start to break down. The high energy description incorporates the following important physical ingredients: i) a mass cut-off in the definition of the \( \pi TFF \) from the \( \pi DA, M, \frac{2}{M} \) which, interpreted from the point of view of constituent models, takes into account the constituent mass, transverse momentum effects and also higher twist effects; ii) a flat \( \pi DA \) at low energies in line with chiral models \([11, 12, 15]\) and recent proposals \([2, 3]\); iii) eventually an additional twist three term into the definition of the \( \pi TFF \) in the high energy description parameterized by a unique constant \( C_3 \); iv) the two descriptions have to match at an energy scale \( Q_0 \); this scale is universal and should be the same for all observables. Though our scheme is not based in the use a hadron model, we have presented in the Appendix a simple model calculation to illustrate
FIG. 5: Same as in Fig 4 for the $Q^2$ region under 17 GeV$^2$. The dashed-line corresponds to the $C_3$ contribution. The short dashed-line is the experimental parametrization $\xi$ for $Q^2 < 1$ GeV$^2$.

the contents of the procedure.

We have seen that, as a consequence of soft pion theorems, the $\pi DA$ and $\pi VPD$ are equal at low energies up to the matching scale $Q_0$. Moreover, chiral models indicate that in the chiral limit both distributions are flat, more precisely, $\phi_\pi (x, Q_0) = q_V (x, Q_0) = 1$. The flatness of the $\pi VPD$, which implies that the probability of finding a quark of any relative momentum fraction $x$ is the same, is justified by the fact that in the chiral limit quarks and pions are massless and therefore there is no mass scale to which the momentum distribution can attach. The different type of evolution followed by these two distributions hides the relation between them. Nevertheless, the equality between the $\pi DA$ and the $\pi VPD$ at $Q_0$ scale allows us to determine the matching scale using the parton distributions. From previous studies $[17, 22, 23]$ we can fix this scale at $Q_0 = 0.355$ GeV. Nevertheless, more elaborated studies $[19–21]$ indicates that this matching scale cannot be one in which the constituent quarks are purely valence but require additional sea and gluon components. Theses studies push the matching scale at $Q_0 \sim 1$ GeV.

Using $Q_0 = 0.355$ GeV as matching point, the experimental results are well reproduce up to 15 GeV$^2$, but it is difficult to accommodate the higher momentum results. If we adopt this philosophy, the BaBar data, if confirmed, might imply some new type of contributions $[6]$. Using $Q_0 = 1$ GeV as matching point, the higher momentum results are well reproduced, but with a slope which is too small, and the lower momentum data are overestimated. Nevertheless this last situation can be corrected in a natural way if we assume some additional contribution from twist three.

The calculations shown prove that the BaBar results can be accommodated in our scheme, which only uses standard QCD ingredients and low energy data. It must be emphasized that in order to have a good description higher twist effects are important as the modification from Eq. (11) to Eq. (22) signals. It must be also noted that the matching scale is as high as 1 GeV, a feature which was also the case in the description of parton distributions when precision was to be attained. With these ingredients our calculation shows an excellent agreement with the data and points out that the average value of the highest energy data point is too large, a conclusion reached by other analyses $[4, 5]$.

The relative high value of $M = 0.620$ GeV can be understood on the basis that it includes the constituent quark mass, the mean value of the transverse quark momentum and other higher twist contributions. The $C_3$ term is relatively small. Its effect is to reduce the value of the contribution to the $\pi TFF$ of twist two only for low $Q^2 < 5$ GeV$^2$. Our results are very stable with respect to variations of these parameters.

Let us conclude by stressing that we have developed a formalism to describe the $\pi TFF$ based on the philosophy that two descriptions, a perturbative and a non perturbative can be matched in a physically acceptable manner at a certain scale $Q_0$. The idea of the formalism is that one can use models or effective theories to describe the non
perturbative sector while QCD to describe the perturbative one. In here we have preferred to use data for the low energy sector to avoid model dependence, but in other observables, and specially in predictions, models can be used for estimates. Moreover, in order to describe the data we have seen that a matching scale of 1 GeV was favored over the one of 0.355 GeV that we would obtain if only valence constituents were assumed to describe low energies. This implies that the description of high precision data requires sophisticated effective theories (models) at low energies. We have also discovered that higher twist effects (parametrized in our case by $M$ and $C_3$) are small but crucial in order to attain good descriptions. Finally we can assert that our description of the data is excellent all over although points out to a too large average value of the highest $Q$ points in the data.

Appendix A: The triangle diagram.

The easiest model to evaluate the $\pi TFF$ is to use the triangle diagram defined in Fig. 1. There are two diagrams, the one depicted an another with the photons exchanged. The amplitude for the process can be defined as

$$\mathcal{T} = 4 \pi \alpha \varepsilon^\mu \varepsilon^{\nu} q^\pi q'^\sigma \varepsilon_{\mu\nu\rho\sigma} F(q, q')$$ \hspace{1cm} (A1)

In a straightforward calculation\(^3\),

$$F(q^2, q'^2) = 8 m_\pi g_{\pi qq} I(m, q^2, q'^2),$$ \hspace{1cm} (A2)

where

$$I(m, q^2, q'^2) = i \int \frac{d^4 \ell}{(2\pi)^4} \frac{1}{(\ell^2 - m_q^2 + i\epsilon) \left[(q - \ell)^2 - m_q^2 + i\epsilon\right] \left[(q' + \ell)^2 - m_q^2 + i\epsilon\right]} \hspace{1cm} (A3)$$

$q_\mu$ and $q'_\mu$ are the photon momenta, which, in this expression, can be real or virtual photons. Here, $m_q$ is the constituent quark mass, $g_{\pi qq}$ the pion-quark coupling constant, $q$ and $q'$ the photons momenta. The small virtuality of one of the photons implies that $q'^2 = 0$, and we define $F(Q^2) = F(q^2, 0)$ with $Q^2 = -q^2$. In the chiral limit, $m_\pi = 0$, we can use the Goldberger-Treiman relation, $g_{\pi qq}/m_q = \sqrt{2}/f_\pi$, obtaining

$$F(Q^2) = \frac{\sqrt{2} m_q^2}{2 \pi^2 f_\pi} \int_0^1 dx \frac{1}{Q^2 x \sqrt{1 + 2 u}} \log \frac{1 + u + \sqrt{1 + 2 u}}{1 + u - \sqrt{1 + 2 u}}$$ \hspace{1cm} (A4)

where $u = 2 m_q^2/(Q^2 x^2)$.

The behavior of the form factor for small $Q^2$ values follows from the previous equation,

$$F(Q^2) \xrightarrow{Q^2 \to 0} \frac{\sqrt{2}}{4 \pi^2 f_\pi} \left( 1 - \frac{Q^2}{12 m_q^2} \right)$$ \hspace{1cm} (A5)

Therefore, we have $F(0) = \sqrt{2}/(4\pi^2 f_\pi) = 0.273$ GeV\(^{-1}\), and, from Eq. (A5), $m_q = m_\pi/\sqrt{12} \approx 0.220$ GeV.

We can also look for the asymptotic behavior. The denominator of Eq. (A4) can be developed in the form $x \sqrt{1 + 2 u} \sim x + 2 m_q^2/(Q^2 x)$. Comparing this expression with Eq. (A5), we have $M = \sqrt{2 m_q^2/x} \sim 2 m_q = 0.44$ GeV. Performing the integral in Eq. (A4) we have

$$Q^2 F(Q^2) \xrightarrow{Q^2 \to \infty} \frac{m_q^2}{2 \sqrt{2} \pi^2 f_\pi} \log \frac{Q^2}{m_q^2} \left[ \frac{\log Q^2}{m_q^2} + \frac{4 m_q^2}{Q^2} + ... \right] ... .$$ \hspace{1cm} (A6)

\(^3\) A detailed calculation of this process is shown in ref. [35]. We need to replace there $e^2$ by $N_c (e_u^2 - e_d^2) = e^2$, since in our case we have quarks in the loop.
Therefore, the model calculation gives a wrong asymptotic behavior. We have $Q^2 F(Q^2) \sim 0.54 \text{ GeV}$ for $Q^2 \sim 30 \text{ GeV}^2$ which is a very large result, and the form factor grows as $(\log Q^2/m_q^2)^2$ for large $Q^2$ values. Comparing this expression with Eq. (22), we obtain $C_3 = \sqrt{2m_q^4 \log (Q_0^2/m_q^2)} / \pi^2 f_\pi \sim 0.78 10^{-2} \text{ GeV}^3$, which is consistent with the values for $C_3$ used in the text.
