Synopsis We show how normal incidence X-ray total scattering can be used to obtain high quality Pair Distribution Functions from amorphous and crystalline thin films on much thicker substrates, opening for a range of studies of the local structure in film materials.

Abstract By means of normal incidence, high flux and high energy x-rays, we have obtained total scattering data for Pair Distribution Function (PDF) analysis from thin films (tf), suitable for local structure analysis. By using amorphous substrates as support for the films, the standard Rapid Acquisition PDF setup can be applied and the scattering signal from the film can be isolated from the total scattering data through subtraction of an independently measured background signal. No angular corrections to the data are needed, as would be the case for grazing incidence measurements. We illustrate the ‘tfPDF’ method through studies of as deposited (i.e. amorphous) and crystalline FeSb\textsubscript{3} films, where the local structure analysis gives insight into the stabilization of the metastable skutterudite FeSb\textsubscript{3} phase. The films were prepared by depositing ultra-thin alternating layers of Fe and Sb, which interdiffuse and after annealing crystallize to form the FeSb\textsubscript{3} structure. The tfPDF data show that the amorphous precursor phase consists of corner-sharing FeSb\textsubscript{6} octahedra with motifs highly resembling the local structure in crystalline FeSb\textsubscript{3}. Analysis of the amorphous structure allows predicting whether the final crystalline product will form the FeSb\textsubscript{3} phase with or without excess Sb.
present. The study thus illustrates how analysis of the local structure in amorphous precursor films can help to understand crystallization processes of metastable phases and opens for a range of new local structure studies of thin films.

Keywords: Total Scattering; Pair Distribution Function Analysis; Thin Films

1. Introduction

Thin films are fundamental in applications from electronics to catalysis to tribology in structural materials. (Nomura et al., 2004, Tang et al., 1989, O'Regan & Gratzel, 1991, Ginley & Bright, 2000) Even in basic science the thin-film geometry allows the generation of structures that are normally metastable. For example, advanced methods in thin film preparation such a chemical vapor deposition, (Hampdensmith & Kodas, 1995, Hunt et al., 1993) atomic layer deposition (George, 2010) and molecular beam epitaxy (Panish, 1980) have in recent years made it possible to prepare new, advanced functional materials with applications in e.g. thermoelectrics, semiconductors, and multiferroics. (Chiritescu et al., 2007, Ramesh & Spaldin, 2007, Nomura et al., 2004, Fortunato et al., 2012) Compounds, which are unstable or metastable in the bulk state, can by means of these atomic-layer engineering techniques be prepared as thin films, opening for a whole new realm of materials. When films are single crystalline, powerful methods such as Coherent Bragg Rod Analysis (Yacoby et al., 2002) and x-ray standing wave analysis (Cowan et al., 1980) can yield significant quantitative information about the ordered structure at the surface.(Eom et al., 1992) However, if the films are nanocrystalline or amorphous the situation becomes much more difficult. Here we describe a straightforward approach to obtain quantitative atomic pair distribution functions (PDF) from nanocrystalline and amorphous thin films yielding important local and intermediate-range structural information from films.

When preparing thin films (10-1000 nm), the precursor compounds are typically deposited on a much thicker substrate of e.g. Si, SiO₂ or Al₂O₃. This sample geometry challenges the conventional methods for structural analysis using x-ray diffraction, as data collected using standard scattering configurations (i.e. Debye-Scherrer or Bragg-Brentano setups) are dominated by scattering from the substrate. To avoid this, grazing incidence (GI) x-ray diffraction methods are generally applied for thin film structure analysis. (Lim et al., 1987) GI measurements are done with an incident x-ray angle close to the critical angle for total external reflection, which allows the beam to illuminate as much of the thin film as possible whilst minimizing penetration of the beam into the substrate and maximizing the signal from the film. However, not only are the experiments challenging because of the very small critical angles for hard x-rays, the grazing incidence geometry complicates analysis of the data as angular dependent corrections for the penetration depth and the amount of illuminated
sample/substrate must be made before quantitative information can be extracted. While e.g. Rietveld analysis can be done after careful corrections and provide valuable structural insight,(Quaas et al., 1998, Simeone et al., 2011) most of the x-ray analysis done for thin films is qualitative and used mainly for identification of crystalline phases by considering the Bragg peak position. This approach is not adequate to characterize e.g. the complex nanostructures present in modern materials, which may not possess long-range order.(Billinge & Kanatzidis, 2004)

In recent years, PDF analysis has become a standard technique for characterization of local structure in bulk and nanomaterials. PDF yields structural information from amorphous, nanostructured and crystalline materials, and PDF studies have led to a breakthrough in our understanding of materials structure and reactions in materials chemistry.(Billinge & Levin, 2007) In the same way, for thin films, local structural analysis could yield important information about local structure, crystallization processes, and modifications from bulk structure of films. However, for PDF data corrections, grazing incidence geometry highly complicates the data analysis.(Peterson et al., 2003) So far, to the best of our knowledge, PDF has therefore not been successfully applied to analysis of thin films in grazing incidence. We therefore set out to develop a method that can be used to do quick, routine PDF analysis of thin films, here referred to as tfPDF. We show that by using high flux, high energy x-rays from third generation synchrotron sources, normal incidence total scattering measurements can be used to extract reliable PDFs from thin films on amorphous substrates. The measurements can be done in transmission through both the sample and the substrate using the standard rapid acquisition PDF (RA-PDF) setup with a large area detector, (Chupas et al., 2003) making tfPDF readily available to use for a range of thin film materials.

Here, we have investigated amorphous and crystalline FeSbₓ films to illustrate the feasibility of tfPDF. Deposition of alternating ultra-thin Fe and Sb layers on a flat substrate gives an amorphous film, which upon annealing crystallizes to form FeSb₂ or FeSb₃, depending on the thickness of the alternating Fe/Sb layers as described by Williams et al.(Williams et al., 2001) The FeSb₃ skutterudite structure is metastable, and consists of corner-sharing FeSb₆ octahedra only (Figure 1A), whereas the thermodynamically stable FeSb₂ marcasite structure has both corner and edge-sharing octahedra.(Hornbostel et al., 1997) (Figure 1B). We set out to use tfPDF to study the local structure in the as-deposited films that leads to the metastable phase FeSb₃, to investigate the diffusion between the Fe/Sb layers, and the relation between the precursor layering and the final, crystalline product. Our studies give new insight into the crystallization of the metastable FeSb₃ phase and open for a range of new investigations of film materials.
2. Experimental details

2.1. Preparation of FeSbx

The FeSb3 samples were synthesized using layered deposition as described in detail elsewhere. (Williams et al., 2001) The Sb and Fe precursors were deposited on 170 μm thick amorphous borosilicate glass slips using the Modulated Elemental Reactant (MER) synthesis method on a custom-built deposition system. (Harris et al., 2005) Antimony was deposited from a Knudsen effusion cell whereas an iron source was evaporated using an electron gun. A pressure below 5x10^-7 torr was maintained during deposition. Deposition rates were monitored from quartz crystal microbalances and shutters installed above each source were sequentially opened and closed to achieve a layered precursor of the desired thickness. The deposition parameters were calibrated to allow for targeted composition ratios and bilayer thicknesses between Fe and Sb. After precursor layer deposition, the films were annealed in nitrogen for 30 minutes at 200 °C. Compositional data was obtained with an electron probe microanalyzer, using a thin-film technique described previously. (Phung et al., 2008) Two sets of samples were prepared with varying Fe/Sb ratio, as listed in Table 1. The Fe layers, whose calibrated thickness is 1.0-1.1 Å, are believed to consist of a Fe monolayer covering the much thicker Sb layers. The as-deposited samples are marked A for amorphous (i.e. sample 1A and 2A) whereas annealed samples are marked C for crystalline (i.e. 1C and 2C).
Table 1: Sample list

| Sample name | Structure                  | Layer thickness | Fe/Sb ratio | Film Thickness |
|-------------|----------------------------|-----------------|-------------|---------------|
| 1A          | As-deposited, amorphous    | Fe: 1.1 Å       | 0.21        | 3600 Å        |
|             |                            | Sb: 17.0 Å      |             |               |
| 1C          | Annealed, crystalline      | Fe: 1.1 Å       | 0.21        | 3600 Å        |
|             |                            | Sb: 17.0 Å      |             |               |
| 2A          | As-deposited, amorphous    | Fe: 1.0 Å       | 0.33        | 3600 Å        |
|             |                            | Sb: 12.0 Å      |             |               |
| 2C          | Annealed, crystalline      | Fe: 1.0 Å       | 0.33        | 3600 Å        |
|             |                            | Sb: 12.0 Å      |             |               |

2.2. tfPDF measurements

Figure 2 shows the setup used for normal incidence thin film PDF measurements. The films are mounted perpendicular to the beam in a simple sample holder for flat plate samples, using Kapton tape to hold the film and substrate in place. The holder was mounted and centered in the goniometer so that the beam passes through the substrate before hitting the thin film.

Data collection was carried out at the XPD beamline (X-ray Powder Diffraction, ID28) at the NSLS-II synchrotron, Brookhaven National Laboratory, USA, with a photon wavelength of 0.235 Å and a Perkin Elmer amorphous silicon detector, measuring 40 by 40 cm² i.e. in a setup similar to the usual RA-PDF geometry, making the experiments especially straightforward. In addition to the thin films, the scattering pattern from a clean substrate of the same material was measured, allowing background subtraction to be done. This approach has not been possible before because of the very low signal-background ratio in the data from a thin film sample. However, through the use of the high-fluxes of hard x-rays available at modern synchrotrons, and use of the latest data reduction methods that allow very dilute signals to be successfully separated from large host signals, we show that this approach is now possible.

Calibration of detector distance and beam center was carried out using a standard Ni sample on Kapton tape, mounted in the sample holder. Data collection took 15 minutes for each sample, and was made with correction for the dark current signal. Total scattering data were also measured for reference samples of powders of amorphous and crystalline FeSb₃ packed in a Kapton capillary as described in the supplementary information.
2.3. Data analysis

The PDFs were obtained from the 2D data using SrXgui (Yang et al., 2014) and PDFgetX3 (Juhas et al., 2013) in xPDFsuite (Yang et al., 2015) as described below, with $Q_{\text{min}} = 0.8$ Å$^{-1}$, $Q_{\text{max}} = 17.5$ Å$^{-1}$, $Q_{\text{max-instrument}} = 17.5$ Å$^{-1}$ and $r_{\text{poly}} = 0.9$ Å. Modeling of the PDFs was done using PDFgui, (Farrow et al., 2007) where the FeSb$_3$ structure was refined in space group Im-3, (Hornbostel et al., 1997) FeSb$_2$ in space group Pnnm and Sb in space group H-3m. For each phase, a scale factor was refined along with unit cell parameters and symmetry allowed atomic positions. Isotropic Debye-Waller factors were also refined for Fe and Sb in each phase and correlated motion was taken into account by including the $\delta 2$ parameter in the model. The coherence lengths of the crystalline phases were modeled by applying a spherical envelope to the model after taking instrumental dampening into account by modelling of a bulk Ni standard.

3. Results and discussion

3.1. Obtaining the tfPDF: Amorphous and crystalline FeSb$_3$ films

We firstly illustrate that reliable PDFs can be obtained from thin films on amorphous substrates, using the data obtained for sample 1A (amorphous) and sample 1C (crystalline) as an example. Figure 3A (black line) shows the total x-ray scattering pattern from sample 1C, i.e. a 360 nm thin crystalline FeSb$_x$ film. The thickness of the borosilicate substrate was 170 μm and thus, at normal incidence, the irradiated FeSb$_x$ film only corresponds to ca. 0.21% by volume of the total sample in the x-ray beam. Accordingly, the scattering pattern shows only a very weak signal from the crystalline film while the
majority of the scattered intensity is from amorphous borosilicate. In order to isolate the contribution from the FeSb$_x$ film, the substrate contribution was determined by measuring the scattering pattern from a clean substrate, shown by the red line in Figure 3A. The Bragg peaks from the film are barely visible on top of the large substrate contribution, but become clearer after subtracting the background signal as shown in the difference between the two signals, plotted as the green curve in Figure 3A. As shown on the expanded scale in Figure 3B, Bragg peaks from crystalline FeSb$_3$ are visible in the difference curve to $Q$-values at ca. 10 Å$^{-1}$.

Figure 3: A) Normalized data collected for sample 1C (black) and a clean substrate (red). The difference curve is shown in green and is plotted on an expanded scale in B. C) Normalized data collected for sample 1A (black) and the clean substrate (red), and difference between the two (green), also shown on an expanded scale in D.
The scattering pattern from the amorphous precursor to the crystalline film is plotted in Figure 3C-D, again showing the total signal including the background contribution (C), as well as the weak signal from the amorphous FeSb₃ precursor (D). Here, only diffuse scattering features from the amorphous film are present, but despite this, background subtraction was still sufficient to isolate the broad peaks from the Fe/Sb signal.

PDFs from the total scattering data were obtained using PDFgetX³ in xPDFsuite. (Yang et al., 2015) The program uses an ad hoc data reduction algorithm, making fast, reliable data processing possible as individual corrections for e.g. Compton scattering and fluorescence are not needed. Instead, corrections for all long wavelength effects in the total scattering signal are accounted for by polynomial fitting as described in detail in Juhas et al. (Juhas et al., 2013) This approach to data analysis makes PDFgetX³ very well suited for data where background scattering constitutes the majority of the total signal as was previously shown for nanoparticles in very dilute systems. (Terban et al., 2015) Apart from correcting for the physical effects as mentioned above, the polynomial fitting applied in PDFgetX³ can eliminate small differences between the measured background (in this case the clean substrate) and the background contribution in the sample pattern, if they are sufficiently low frequency oscillations. For standard PDF samples, these effects are on a much smaller scale than the actual signal in question and do not pose any problems in the resulting PDF. However, for small signals, such as from thin films on thick substrates, deviations such as these can be on the same scale or larger than the signal from the sample and dominate the signal after taking the difference. The PDFgetX³ algorithm proves to be a powerful method to make these corrections that are crucial to obtain a reliable PDF from the film.

The corrected, reduced total scattering functions $F(Q) = Q(S(Q) - 1)$ are shown in Figure 4A, for the crystalline and amorphous FeSb₃ thin films. The substrate contribution was subtracted in $Q$-space and the $F(Q)$ thus represents the signal just from the film. Clear signals with a very low noise level even at relatively high $Q$-values are seen for both the crystalline and amorphous samples. The good data quality leads to high quality PDFs for both the amorphous and crystalline films as shown in Figure 4B, which were obtained by Fourier transforming the $Q$-range from 0.8-17.5 Å⁻¹. The PDF arising from a clean substrate is seen in Figure 4C. Here, a very intense peak is observed at ca. 1.7 Å, corresponding to the Si-O bond distance in the borosilicate glass. Inadequate background subtraction would lead to a peak at this position in the final PDF (or a negative peak when over-subtracting), but no such features are seen in Figure 4B. Minor ripples are observed which may arise from small difference between the substrates, but these are easily distinguished from the film signal.

Figure 4D compares the tfPDF for the amorphous FeSb₃ samples obtained from a similar sample, measured in a standard PDF setup as described in the supplementary information. Clearly, the tfPDF reproduces the features from the high quality capillary PDFs, showing that reliable PDFs are being obtained even from the 360 nm thick thin-films. The tfPDF has a higher noise level than that from the
capillary data, but the structural features can easily be distinguished. Minor differences between peak intensities are observed in the 3-5 Å range, but this may be real, due to differences in Fe/Sb composition.

Figure 4: A) Reduced total scattering function $F(Q)$ for sample 1A (black) and 1C (red). B) Reduced pair distribution function $G(r)$ for 1A (black) and 1C (red). C) $G(r)$ obtained for clean substrate. D) Comparison between the tPDF for sample 1A and a powder sample of similar composition, where the data were obtained for a sample measured in a standard capillary.
3.2. Structures in the FeSb₂ system: Sample 1

After having established the reliability of the tfPDFs by comparison with the PDF from a capillary setup, structural information can be extracted from the data. Firstly, we analyse the tfPDFs obtained from sample 1C, i.e. the annealed film discussed above. Figure 5A shows a fit of the FeSb₃ phase to the PDF from the crystalline film. The fit gives a $R_w$ value of 32%, showing large discrepancies between the model and data. By including crystalline Sb into the model, the $R_w$ value is reduced to 22%, and as can be seen in Figure 5B, the model now agrees well with the experimental PDF in the high $r$-range. The refined parameters are given in Table 2. The fit shows that the crystalline fraction of the sample contains 73% FeSb₃ and 27% of elemental antimony. However, Figure 5B also illustrates differences between the experimental and calculated PDF in the low $r$ region. Especially, the high intensity of the peak at 2.9 Å is not fitted well, and smaller disagreements are also seen up to ca. 7 Å. Considering the structure of the Sb, the peak at 2.9 Å corresponds to the shortest Sb-Sb distance as illustrated in the supplementary information. The PDF thus indicates that apart from crystalline FeSb₃ and Sb included in the model, a fraction of amorphous Sb with only short-range order is also present in the sample. This agrees well with the elemental composition: In the total sample, the Fe/Sb ratio is 0.21 whereas in the model including only the crystalline phases, this ratio is ca. 0.30. Neither the I(Q) or the G(r) showed any signs of significant texture effects in the sample and preferred orientation is not believed to contribute significantly to the misfit in the local structure.

The observed range of structural coherence, modelled using a spherical particle envelope function, of the crystalline Sb component and the FeSb₃ phases refine to 11 and 15 nm, respectively. For the PDF to yield quantitatively reliable structures, the sample must be scattering isotropically, which is typically the case for a fine-grained powder and for nanocrystalline samples, and we have assumed that the thin film is also isotropic at the nanoscale. Based on the quality of the fits to the data, this seems to be true: there is no pronounced crystalline texture that results in some Bragg and PDF peaks to be anomalously intense and others anomalously weak. However, care should be taken in general in a thin-film where the anisotropy of the sample geometry may result in anisotropy in the film structure. In our tfPDF measurement geometry, the scattering vector lies predominantly in the plane of the film and so the structure is being probed predominantly in this direction (the RA-PDF experiment is not carried in symmetric transmission so the scattering vector is not perfectly in the film plane). The measured PDF will then be a superposition of all the structural variants that exist as a function of film thickness, and anisotropies in things such as structural coherence will be sampled in a complicated way, with a greater contribution from the out-of-plane behavior in the high angle, high-$Q$ region. These effects may be deconvoluted somewhat by taking multiple measurements at different incident angles with respect to the film, though this was not done in the present case. For example, we note that the observed structural coherence of 10-15 nm is 5x larger than the separation of the initial amorphous Fe/Sb layers, which alternated at ca. 20 Å. Williams et al. report that the layered structure...
is preserved in the amorphous phase. Our result would suggest that the layering is largely removed after annealing despite the remaining amorphous Sb component. However, some persistent layering cannot be ruled out from our current dataset for this reason.

Figure 5: Fits (red) to the experimental PDF from sample 1C (black). The green line shows the difference curve. A) Only FeSb$_3$ included in the model. B) FeSb$_3$ and crystalline Sb included in the model.

Table 2: Refined parameters for the crystalline

| Parameter                  | Value            |
|----------------------------|------------------|
| $R_W$                      | 23.7%            |
| Weight percent, FeSb$_3$   | 72.7%            |
| $a$, FeSb$_3$              | 9.185 Å         |
| Crystallite size, FeSb$_3$ | 15.1 nm         |
| $y_{Sb}$, FeSb$_3$         | 0.337            |
| $Z_{Sb}$, FeSb$_3$         | 0.159            |
| $U_{iso,Sb}$, FeSb$_3$     | 0.0174 Å$^2$    |
| Weight percent, crystalline Sb | 27.3%        |
| $c$, Sb                    | 4.299 Å         |
| Crystallite size, Sb       | 11.291 Å        |
| $z$, Sb                    | 0.767            |
| $U_{iso,Sb}$, Sb           | 0.0098 Å$^2$    |
| $\delta^2$                 | 4.08 Å          |

*The $\delta^2$ parameters for the two phases, expressing correlated motion, were constrained to the same value.

Having analysed the structure of the crystalline 1C film, we can now use the structure models to gain a better understanding of the atomic arrangement in the as-deposited precursor film, i.e. 1A. Figure 6A shows a comparison between the low $r$ regions of the tfPDFs from both films. Interestingly, the
local structure of the amorphous film is closely related to the crystalline structure as the first 4 main peaks overlap. By considering the atomic pairs leading to the peaks in the crystalline structure, we can identify the local structural motifs in the amorphous film. As seen in Figure 1A, the FeSb₃ structure consists of corner sharing FeSb₆ octahedra, making up the full skutterudite lattice. A cutout of the FeSb₃ unit cell is shown in Figure 6B with selected interatomic distances marked and tabulated in the supplementary information. The nearest neighbour Fe-Sb distance in FeSb₃ is ca. 2.6 Å, (marked in pink in Figure 6B) which is seen as a clear peak in the PDFs from both the crystalline and amorphous phases. After deposition of the individual Fe/Sb layers, the metals thus immediately diffuse at room temperature to form an alloyed, amorphous structure between the Fe/Sb layers rather than staying as separate phases. The nearest intra-octahedral Sb-Sb distances in the crystalline FeSb₃ structure arising from the edge length in the FeSb₆ octahedra make up the broad peak centred at 3.5 Å, marked in orange in Figure 6B. Again, this peak can clearly be found in the PDF from the amorphous sample, largely overlapping with that from the crystalline PDF. The longest Sb-Sb distance in the FeSb₆ octahedra is at 5.1 Å (marked in green), where a small peak can also be identified, thus illustrating how all intra-octahedral distances can be found in the PDF from the as-deposited sample.

Figure 6: A) Comparison between the PDF obtained from sample 1A (black) and sample 1C (red). Pairs contributing to the low r region are indicated with arrows, and color coded with the bond illustrated in B) showing a cut-out from the FeSb₃ unit cell, with corner-sharing FeSb₆ octahedra. Iron is shown in red and antimony in blue.

The intense PDF peak at 2.9 Å originates mainly from the shortest Sb-Sb distances in the elemental crystalline Sb phase as described above, marked with black in Figure 6A. This peak is clearly present in the amorphous phase, so apart from the interdiffused Fe-Sb structures, the amorphous phase appears to also contain a fraction of amorphous Sb not atomically coordinated to Fe. In crystalline Sb, the 2nd nearest neighbor Sb-Sb distance is at 3.34 Å, and from the theoretical PDF from Sb metal, this
peak should have ca. 80% of the intensity of the peak at 2.9 Å. However, this peak is not clear in the PDF from sample 1A, indicating that the local structure of the amorphous Sb fraction in the as-deposited sample does not resemble that of crystalline Sb, where the atoms are arranged in layers of 6-membered rings.

As indicated in Figure 6A and explained in more detail in the supplementary information, the PDF peak at 4.3 Å in crystalline FeSb$_3$ arises from a number of inter-octahedral correlations, one shown in red in Figure 6B. A broad peak in the same region is seen in the PDF from the amorphous phase. In crystalline FeSb$_3$, an inter-octahedral Sb-Sb distance marked in cyan in Figure 6 furthermore give rise to a weak peak at ca. 2.9 Å. However, compared to the Sb-Sb distance in crystalline Sb metal, this is only a minor contribution to the total PDF of the crystalline sample, and we cannot distinguish this from the elemental Sb-Sb peak in sample 1A.

The observation of the existence of FeSb$_6$ octahedra as well as amorphous Sb points to a structure where amorphous Sb structures with only short range order coexist with a disordered, corner-sharing FeSb$_6$ octahedra. The local structure of the amorphous precursor before thermal annealing thus highly resembles that of the metastable FeSb$_3$ phase, explaining the possibility to synthesize it from the layered precursors.

### 3.3. Structures in the FeSbx system: Sample 2

Sample 2 was prepared with slightly lower antimony content than sample 1. Figure 7 compares the PDFs from sample 1A and 2A, i.e. the two amorphous samples. While some of the peaks discussed above are also evident in the 2A PDF, we also observe clear differences in the local structure. The first peak at 2.6 Å again corresponds to the Fe-Sb distance in FeSb$_6$ polyhedra and peaks from the Sb-Sb distances in the octahedra (at ca. 3.5 Å and 5.1 Å, see Figure 6) are also seen. Furthermore, a contribution at 2.9 Å is also present, corresponding to the first Sb-Sb distance in metallic Sb as discussed above. However, compared to 1A, this peak is much less dominant, indicating a smaller contribution of Sb not coordinated to Fe. This agrees with the measured compositions, where the Fe/Sb ratio is 0.33. We also see a difference in the width and position of the peak at ca. 4.6 Å, which we above ascribed to correlations between the individual octahedral. Possibly, the lower Sb content changes the local structure around the octahedral units.
The appearance of the PDF from sample 2A indicates that the corresponding annealed sample 2C will contain a smaller Sb content than sample 1C. This is confirmed when modelling the PDF, as a two-phase fit with FeSb$_3$ and Sb results in crystalline phase fractions of 99% and 1%, respectively, thus effectively suppressing the Sb phase completely. However, interestingly, the fit of the FeSb$_3$ phase is still of poor quality, giving $R_w=35\%$ and large deviations as seen in Figure 8A. When introducing the thermodynamic phase in the phase diagram, FeSb$_2$, the fit improves considerably (Figure 8B) giving $R_w$ of 25%. The refined parameters for this fit are given in Table 3. The refined phase fractions are 73% FeSb$_3$ and 27% FeSb$_2$, with the coherence length in the FeSb$_2$ phase being ca. 7 nm. The coherence length of the FeSb$_3$ phase refines to ca. 50 nm, which is well above the reliable limit for size determination but indicates that this component forms very large crystallites. The lower Sb content in the precursor thus has two effects: Suppression of crystalline Sb while forming a phase mixture between the thermodynamic FeSb$_2$ phase and the metastable FeSb$_3$ as well as allowing the FeSb$_3$ to grow into a bulk phase.
### 4. Conclusion

PDFs have been obtained from supported thin film samples, using normal incidence x-ray diffraction measurements in a standard RA-PDF setup. The use of high flux, high energy x-rays and careful background subtraction in $Q$-space make it possible to get a clear scattering signal from amorphous, nanocrystalline and polycrystalline films down to a thickness of at least a few hundred nanometers, which by use of $xPDFsuite$ and $PDFgetX3$ can be Fourier transformed into PDFs of high quality. (Yang et al., 2015)

All films studied were deposited on amorphous substrates, as this allows for simple subtraction of the substrate scattering signal without the need to mask intense, orientation dependent scattering signals from single crystal substrates, e.g. silicon wafers. No angular dependent corrections are needed, as would be the case for grazing incidence measurements. By use of $PDFgetX3$, where *ad hoc* corrections for fluorescence, Compton scattering and any other non structural effects are done, PDFs can be obtained quickly in a robust manner. The thin films that have been studied here are all *ca.* 360 nm thick, but PDFs from even thinner films may also be obtained, as long as background subtraction of the substrate signal is done.

The characterization of thin film has so far been limited by the need for grazing incidence techniques, which is still to be reported for PDF analysis. In some cases, the film can be isolated from the substrate and standard characterization techniques can be used, but most often, this is not possible due to the small mass of sample present as film. tfPDF thus opens the way for many new possibilities in materials characterization for thin films. As shown in the case of the FeSbx samples, tfPDF can be...
used to understand the relation between the local structure in amorphous films and the final crystalline product, which will help chemists in controlled synthesis of new, advanced materials, in thin film form. We now plan to use tPDF for in situ studies, where a much deeper understanding of processes like this (diffusion, nucleation, crystallization) can be understood. While the time resolution is limited by longer counting times required for the small amount of sample present in the beam, the new, high flux beamlines at 3rd generation synchrotrons suitable for PDF analysis will allow these studies to be feasible.
