Abstract
The hypoxia-inducible factor-1 (HIF-1) is primarily involved in the sensing and adapting of cells to changes in the O2 level, which is essential for their viability. An increased activity is recognized in the majority of clinical relevant hypoxic/ischemic episodes and human cancers. HIF-1 is considered a central regulator of the adaptation response of cancer cells to hypoxia that makes it a therapeutic target in solid tumors. In this article, the biochemical pathways that are regulated by HIF-1 and the factors that regulate HIF-1 expression are briefly discussed. As targeting HIF-1, may selectively kill tumor cells that adapt to low O2 concentrations.

Keywords: Hypoxia; Hypoxia-inducible factor-1

Introduction
Hypoxia definition
Oxygen deprivation (hypoxia) occurs in tissues when O2 supply via the cardiovascular system fails to meet the demand of O2-consuming cells. Hypoxia occurs naturally in physiological settings (e.g., embryonic development and exercising muscle), as well as in pathophysiological conditions (e.g., myocardial infarction, inflammation, and solid tumor formation) [1].

Hypoxia is the main stimulus for angiogenesis. Hence, hypoxic tumors are significantly more malignant, metastatic, radio and chemoresistant [3]. Hypoxia stimulates angiogenesis by signaling through Hypoxia-inducible factors HIFs [4].

Structure of HIF-1
HIF-1 is a heterodimer composed of HIF-1α and HIF-1β subunits. Whereas HIF-1β is constitutively expressed, HIF-1α expression is induced in hypoxic cells with an exponential increase in expression as cells are exposed to O2 concentrations of less than 6%, which corresponds to a partial pressure (P) of O2 of approximately 40 mm Hg at sea level [5].

The amino-terminal half of HIF-1α (amino acids 1-390) is necessary and sufficient for dimerization with HIF-1β and for DNA binding. HIF-1α is ubiquitinated and subjected to proteasomal degradation in non-hypoxic cells Figure 1. Under hypoxic conditions, the fraction of HIF-1α that is ubiquitinated decreases dramatically, resulting in an accumulation of the protein. A Pro–Ser–Thr rich protein stabilization domain is located between amino acids 429 and 608 of HIF-1α [6], subunits are shown with the basic helix-loop-helix (bHLH) and PER-ARNT-SIM (PAS) domains that are required for dimerization and DNA binding. Also shown for HIF-1α are the amino-terminal (N) and carboxyterminal (C) nuclear localization signal (NLS) and TAD; the oxygen-dependent degradation domain); and sites of interaction with VHL, and p300 and CBP. The double-headed arrow indicates that the hypoxia-inducible factor-1 (HIF-1) is primarily involved in the sensing and adapting of cells to changes in the O2 level, which is essential for their viability. An increased activity is recognized in the majority of clinical relevant hypoxic/ischemic episodes and human cancers. HIF-1 is considered a central regulator of the adaptation response of cancer cells to hypoxia that makes it a therapeutic target in solid tumors. In this article, the biochemical pathways that are regulated by HIF-1 and the factors that regulate HIF-1 expression are briefly discussed. As targeting HIF-1, may selectively kill tumor cells that adapt to low O2 concentrations.

Structure of HIF-1
HIF-1 is a heterodimer composed of HIF-1α and HIF-1β subunits. Whereas HIF-1β is constitutively expressed, HIF-1α expression is induced in hypoxic cells with an exponential increase in expression as cells are exposed to O2 concentrations of less than 6%, which corresponds to a partial pressure (P) of O2 of approximately 40 mm Hg at sea level [5].

The amino-terminal half of HIF-1α (amino acids 1-390) is necessary and sufficient for dimerization with HIF-1β and for DNA binding. HIF-1α is ubiquitinated and subjected to proteasomal degradation in non-hypoxic cells Figure 1. Under hypoxic conditions, the fraction of HIF-1α that is ubiquitinated decreases dramatically, resulting in an accumulation of the protein. A Pro–Ser–Thr rich protein stabilization domain is located between amino acids 429 and 608 of HIF-1α [6], subunits are shown with the basic helix-loop-helix (bHLH) and PER-ARNT-SIM (PAS) domains that are required for dimerization and DNA binding. Also shown for HIF-1α are the amino-terminal (N) and carboxyterminal (C) nuclear localization signal (NLS) and TAD; the oxygen-dependent degradation domain); and sites of interaction with VHL, and p300 and CBP. The double-headed arrow indicates that reduction of Cys800, which is mediated by thioredoxin (TRX) and redox factor 1 (REF-1), is required for the interaction of TAD-C with cofactor p300 or CBP. The relevant amino acid residues are indicated numerically [7,8].

Stabilization of HIF-1
Among recent advances are the discoveries that reactive nitrogen species (RNS) and oxygen species (ROS) participate in stability
regulation of HIF-1alpha and HIF-1 transactivation during normoxia Figure 2. Exposure of various cells to chemically diverse NO donors or conditions of endogenous NO formation under normoxic conditions induced HIF-1alpha accumulation, HIF-1-DNA binding, and activation of downstream target gene expression [9].

Hypoxia could decrease electron-transport rate determining Δψm reduction, increased ROS generation, and enhanced NO synthase. One (or more) of these factors likely contributes to HIF stabilization, that in turn induces metabolic adaptation of both hypoxic cells and mitophagy. Solid lines indicate well established hypoxic changes in cells, whilst dotted lines indicate changes not yet stated. Inset, relationships between extracellular O2 concentration and oxygen tension [10].

HIF-1 and metabolism of carbohydrates in hypoxia: When oxygen becomes limiting, cells reduce mitochondrial respiration and increase ATP production through anaerobic fermentation of glucose Figure 3. Also, hypoxia regulates almost all the enzymes involved in glycogen metabolism in a coordinated fashion, leading to its accumulation as a cellular response to hypoxia [11].

Tumors are exposed to intermittent hypoxia that could induce glycogen accumulation that could contribute to the resistance to cellular response to hypoxia [11].

By stimulating the expression of glucose transporters and glycolytic enzymes, HIF-1 promotes glycolysis to generate increased levels of pyruvate. In addition, HIF-1 promotes pyruvate reduction to lactate by activating lactate dehydrogenase (LDH). Pyruvate reduction to lactate regenerates NAD+, which permits continued glycolysis and ATP production by hypoxic cells. Furthermore, HIF-1 induces pyruvate dehydrogenase kinase 1 (PDK1), which inhibits pyruvate dehydrogenase and blocks conversion of pyruvate to acetyl CoA, resulting in decreased flux through the tricarboxylic acid (TCA) cycle.

Decreased TCA cycle activity results in attenuation of oxidative phosphorylation and excessive mitochondrial reactive oxygen species (ROS) production. Because hypoxic cells already exhibit increased ROS, which have been shown to promote HIF-1 accumulation, the induction of PDK1 prevents the persistence of potentially harmful ROS (ROS) production. Because hypoxic cells already exhibit increased ROS, which have been shown to promote HIF-1 accumulation, the induction of PDK1 prevents the persistence of potentially harmful ROS levels [13]. HIF-1alpha is necessary to support gluconeogenesis during the reparative process [14].

HIF-1 and metabolism of carbohydrates in cancer cell: “waves” of gene expression that promote metabolic changes occur during carcinogenesis, beginning with oncogene-mediated changes, followed by hypoxia-induced factor (HIF)-mediated gene expression, both resulting in the highly glycolytic “Warburg” phenotype and suppression of mitochondrial biogenesis. The third (second oncogene) “wave”...
of adaptation stimulates glutaminolysis, that serves as an alternative pathway compensating for cellular ATP content.

Together with anoxic glutaminolysis it provides pyruvate, lactate, and the NADPH pool (alternatively to pentose phosphate pathway). Retrograde signaling from revitalized mitochondria might constitute the fourth “wave” of gene reprogramming, thereby further promoting malignancy [15,16].

In cancer cells, HIF-1alpha induces over-expression and increased activity of several glycolytic protein isoforms that differ from those found in non-malignant cells, including transporters (GLUT1, GLUT3) and enzymes (HKI, HKII, PFK-L, ALD-A, ALD-C, PGK1, ENO-alpha, PYK-M2, LDH-A, PKFB-3). The enhanced tumor glycolytic flux triggered by HIF-1alpha also involves changes in the kinetic patterns of expressed isoforms of key glycolytic enzymes [17]. Some of the HIF1alpha-induced glycolytic isoforms also participate in survival pathways, including transcriptional activation of H2B histone (by LDH-A), inhibition of apoptosis (by HKII) and promotion of cell migration (by ENO-alpha) [18].

HIF-1alpha action may also modulate mitochondrial function and oxygen consumption by inactivating the pyruvate dehydrogenase complex in some tumor types Figure 4, or by modulating cytochrome c oxidase subunit 4 expression to increase oxidative phosphorylation complexes in some tumor types Figure 4, or by modulating cytochrome c oxidase subunit 4 expression to increase oxidative phosphorylation complexes in some tumor types. In parallel, PDK1-induced entry, glycolytic flux, and conversion of pyruvate to lactate. In addition, in other cancer cell lines [19] (OXPHOS) down-regulation in cancers. Invalidation of p53, very frequent in cancers, decreases the expression of SCO2, involved in cytochrome c oxidase assembly [21]. Cancer energy metabolism and mitochondria play a crucial role in tumor development. Increased glycolysis is a hallmark of most cancer cells. Various factors contribute to the phenomenon of the Warburg effect seen in tumors. Oncogenic alterations (PI3K/Akt) and HIF-1 stabilization result in increased expression of glucose transporters and glycolytic enzymes. Moreover, glycolysis aids in increasing the cellular anabolic processes by shunting intermediates to the pentose phosphate pathway [22], Figure 5.

HIF is a central station for cancer growth: Multiple signals affect transcription, translation or posttranslational modification of HIF-1α. These multiple signals, exemplified for macrophages, affect the protein amount of HIF-1α, the activity of HIF-1α and concomitant target gene expression [23], Figure 6.

Pathways blocking PHD activity are marked in red. Signaling pathways leading to an active HIF-1/β HIF-1α heterodimer formation are given in blue = stimulation; i inhibition.

HIF-1α linker between inflammation and angiogenesis: Hypoxia promotes tumor progression by modulating gene expression. In colorectal tumor cells, COX-2 is transcriptionally induced by hypoxia via HIF-1, and it’s up-regulation contributes to maintaining tumor survival and potentially promoting angiogenesis Figure 7. Thus, COX-2 overexpression can be regarded as a critical adaptive response to hypoxia, which mediates both short- (survival) and long-term adaptation (angiogenesis) [24].

Mutations in Wnt and Ras signaling pathways can induce COX-2 in normoxic a condition, resulting in increased levels of PGE₂, which promotes tumor cell growth/survival and stimulates angiogenesis then activates the MAPK pathway and enhances HIF-1 transcriptional activity, resulting in a potential positive feedback loop that may act to maintain high COX-2 levels under hypoxic conditions [25]. In fast-growing tumors, HIF-1alpha is involved in the activation of numerous cellular processes including resistance against apoptosis, overexpression of drug efflux membrane pumps, vascular remodeling and angiogenesis as it induces a number of genes integral to angiogenesis, e.g. Vascular endothelial growth factor (VEGF) [26]. Figure 8, VEGF can function on various types of cells, such as endothelial cells, hepatic stellate cells, endothelial progenitor cells and hemangiocytes, to induce vascular changes in HCC [27,28]. Endothelial cells (Ecs) proliferate in response to the hypoxia-induced VEGF and other growth factors secreted by the ECs or surrounding cell types, including hepatic stellate cells (HSC, considered liverresident pericytes), leukocytes, hepatocytes and Kupffer cells [29]. VEGF family members Increase vascular permeability; induce EC proliferation; leukocyte adhesion; regulate neovessel lumen diameter. Interaction of the VEGF with the receptor activates signaling pathways, e.g. PI3K/ Akt, Ras/Raf-MEK/ Erk, eNOS/NO, and IP3/Ca²⁺ [30]. VEGF-B specifically controlled endothelial uptake of fatty acids via transcriptional regulation of vascular fatty acid transport proteins that support the renergy requires for metastasis and development of cancer [31]. Irrespective of the trigger for the development both intrinsic (driven by genetic alteration)
Invasion plays a major role in chronic inflammation and may have prognostic value in disease progression [37]. Angiogenesis is a highly regulated process that depends on coordinated signaling by growth factors and cell adhesion receptors. Regulation of HIF-1

HIF-1α possesses bHLH and PAS domains which are involved in dimerization with HIF-1b and DNA binding. The HIF-1α subunit contains two TAD, the N- and the C- TADs. The N-TAD lies within the NLS and dimerization with HIF-1b and DNA binding. The HIF-1α subunit possesses the ability to bind to the promoter regions of target genes, promoting their transcription. The regulation of HIF-1α is mediated by the hydroxylation of proline residues, which is catalyzed by prolyl hydroxylase domain proteins (PHDs). The hydroxylation of proline residues enables the binding of the von Hippel-Lindau E3 ubiquitin ligase (pVHL), leading to the degradation of HIF-1α through the ubiquitin-proteasome pathway. This process is regulated by the oxygen concentration, with decreased oxygen levels stabilizing HIF-1α and allowing it to promote the expression of target genes.

**Figure 9:** Cytokines, chemokines, and growth factors play the lead role in the crosstalk between tumor cells, blood vessel and infiltrating leukocytes.

**Figure 10:** HIF-1α is a bridge between inflammation and angiogenesis.

**Figure 11:** PKD1-dependent histone deacetylases 7HDAC7.

**Figure 12:** Genes induced by HIF-1 in cancer cells.

HIF-1α is a key regulator of cellular responses to hypoxia and plays a critical role in the adaptation to hypoxic environments. It promotes the expression of genes involved in angiogenesis, metastasis, and invasion, thereby facilitating tumor growth and survival.

**Genes induced by HIF-1 in cancer cells**

HIF-1 induces the genes of glucose transporters, enzymes of anaerobic glycolysis, factors and enzymes included in both angiogenesis and metastasis Figure 12.

**Regulation of HIF-1**

HIF-1α possesses bHLH and PAS domains which are involved in dimerization with HIF-1b and DNA binding. The HIF-1α subunit contains two TAD, the N- and the C- TADs. The N-TAD lies within the ODDD. The ODDD regulates the stability of HIF-1α via recognition by the von Hippel-Lindau E3 ubiquitin ligase (pVHL), of the hydroxylation state of Pro402 and/or Pro564 residues. This hydroxylation is catalyzed by the enzyme PHD (prolyl hydroxylase domain protein). Acetylation and extrinsic (driven by inflammatory cells and mediators) pathways result in inflammation and neoplasia. The transcription factors NF-kB, HIF-1α and STAT-3 are key modulators of the inflammatory response that promotes cancer development [32]. Figure 9. The presence of inflammatory components in the microenvironment of most neoplastic tissue most frequently results in enhanced angiogenesis, resistance to hormones (in hormonedependent tumours) and inhibition of adaptive anti-tumour immunity. Tumor cells survival, proliferation and eventually invasion and metastasis are all regulated by inflammatory mediators present at the tumor site [33], Figure 10.

The protein kinase D1 (PKD1), a newly described calcium/calmodulin-dependent serine/threonine kinase, has been implicated in cell migration, proliferation and membrane trafficking. Increasing evidence suggests critical roles for PKD1-mediated signaling pathways in endothelial cells, particularly in the regulation of VEGF-induced angiogenesis [34], Figure 11. Phosphorylation is required for VEGF-induced microvessel sprouting in mouse aorta ring assay [35,36]. Angiogenesis plays a major role in chronic inflammation and may have prognostic value in disease progression [37]. The growth of new blood vessels is a dynamic yet highly regulated process that depends on coordinated signaling by growth factor and cell adhesion receptors [38].

**Genes induced by HIF-1 in cancer cells**

HIF-1 induces the genes of glucose transporters, enzymes of...
of the Lys532 residue by the ARD1 acetyltransferase also favors interaction with pVHL. The hydroxylation state of the Asn803 residue, by the enzyme FIH-1 (factor inhibiting HIF-1) inhibits binding of p300/CREB, a HIF-1a co-activator. S-nitrosation of Cys800, in the C-TAD, also promotes HIF-1 transcriptional activity Figure 13. Three consensus sequences at Lys-391, -477, and -532 may be modified by SUMO. The domain from 531 to 826 has been shown to be phosphorylated [40].

In the presence of oxygen HIFα undergoes prolyl hydroxylation at conserved residues, catalysed by a family of iron(II) (Fe2+) and 2-oxoglutarate (2-OG) dependent prolyl hydroxylase domain (PHD) enzymes leading to recognition by the von Hippel-Lindau (VHL) protein which catalyses ubiquitination, targeting HIFα for proteasomal degradation. In addition, a conserved asparagine residue undergoes hydroxylation, by Factor Inhibiting HIF (FIH), which blocks activation of HIF target genes, as well as having other functions. In hypoxic conditions, HIFα translocates to the nucleus, binds to HIFα and additional co-transactivators to activate transcription of target genes which, in turn, modulate a wide variety of cellular processes [41]. Figure 14. HIF-1 target genes related to blood supply, energy production, growth, metastasis of cancer growth Figure 15.

**Abbreviations**: ADM, adrenomedullin; AK-3, adenylate kinase 3; AMF, autocrine motility factor; ANP, atrial natriuretic peptide; α1B-AR, α1B-adrenergic receptor; CA-9, carbonic anhydrase 9; DEC1 and 2, differentiated embryo-chondrocyte expressed gene 1 and 2; ENG, endoglin; EPO, erythropoietin; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; GLUT-1 and -3, glucose transporter 1 and 3; HK-1, hexokinase 1 and 2; HO-1, heme oxygenase 1; IGF-2, insulin-like growth factor 2; IGFBP-1, -2 and -3, IGF-binding protein 1, 2 and 3; LDH-A, lactate dehydrogenase A; LRPI, LDL-receptor-related protein 1; MMP-2, matrix metalloproteinase 2; NOS-2, nitric oxide synthase 2; P-gp, P-glycoprotein multidrug resistance transporter; PAI-1, plasminogen activator inhibitor 1; PGK-1, phosphoglycerate kinase 1; PI3K, phosphoinositide 3-kinase; uPAR, urokinase plasminogen activator receptor; VEGF-R, VEGF receptor; VEGF [42]. Truncated PAS-containing proteins are translated from the alternative splicing of HIF-1α or HIF-3α mRNA, and bind to the endogenous wild-types of HIF-1α or ARNT, thus competing with HIF-1α/ARNT dimerization. Hence, Inhibition of HIF-1 dimerization [42] Figure 16.

**Conclusion**

HIF-1α is the real play maker in the world of hypoxia, it is a cross link between carbohydrate metabolic cycles, inflammatory pathways and angiogenesis. It provides provided a therapeutic target and maybe even a clinical biochemical marker for diagnosis of cancer.
