Abstract

Background: Open and closed fractures can be associated with posttraumatic or postoperative soft tissue defects caused by initial trauma, operative procedures or infections. This study evaluated the outcomes of postoperative qualities of patients with open or closed lower leg fractures, related soft tissue defects, and subsequent flap coverage.

Methods: We performed a retrospective single-center cohort study in a level 1 trauma center. We analyzed the patients treated from January 2012 through December 2017 and recorded demographics, treatment, and outcome data. The outcome data were measured via patient-reported Foot and Ankle Outcomes Scores (FAOS) and EQ-5D-5L scores.

Results: We included 22 patients with complicated fractures (11 open and 11 closed) and subsequent soft tissue defects and flap coverages. The mean follow-up time was 41.2 months. Twenty-one patients developed infections, and necrosis at the site of surgery manifested in all closed fractures. Therefore, all patients needed soft tissue reconstructions. Preoperatively, 16 patients underwent arterial examinations via angiography and six underwent ultrasound examinations of the venous system. Ten patients had complications involving the flaps due to ischemia and consequent necrosis. The mean EQ-5D index was 0.62 ± 0.27, EQ-5DVAS score was 57.7 ± 20.2. The mean FAOS was 60.7 ± 22.2; in particular, quality of life was 32.3 ± 28.8. The rate of returning to work in our patient group was 37.5% after one year.

Conclusions: Distal tibial fractures often require revisions and soft tissue reconstruction. The evaluated patient population had poor outcomes in terms of function, quality of life, and return to work. Our results imply that the severity of associated soft tissue damage with many revision operations and flap complications lead to a poorer outcome with respect to patients without flap ischemia.

Background

Complex distal lower extremity fractures are frequently associated with soft tissue injuries that require challenging and substantial reconstructions [1]. Therefore, it is of high importance that physicians identify the right course of treatment. Among available options, bone and soft tissue reconstruction and limb rescue both require long-term treatment and have more potential comorbidities than primary amputation [2]. Complicated fractures could be limb-threatening if the arterial flow is reduced because of swelling, trauma, or compression. Arterial injuries have resulted in significant complications for patients with lower extremity fractures requiring flap coverage; however, limb salvage is still effective in most cases [3].

Before performing definitive reconstruction, surgeons must examine and determine the extent of injury and the perfusion status of the affected limb. In open fractures, prompt coverage after bone stabilization reduces the complication rates of open fractures [4–6]. In a case series regarding classification schema, Gustilo et al. described patients with ischemic limbs requiring emergency revascularization (type IIIC) as having the worst prognosis of all patients requiring limb salvage [6].

This study investigated the outcomes of qualities of reconstruction with lower leg fractures of patients who required free-flap coverage, to see the relationship between the postoperative outcomes and different qualities like mobility, pain, recovery, sports, and the quality of life.

Methods

Study aim, setting, and design

We performed a retrospective monocentric study at a level 1 trauma center with the aim of evaluating
postoperative outcomes in patients who required soft tissue reconstruction for lower leg fractures. Patient-reported outcomes, including quality of life (QoL) and the ability to return to work, were assessed via questionnaires. Follow-up scores were evaluated in the outpatient clinic, via telephone interview, or via declarations and forms mailed to and completed by patients. The minimum follow-up was 22 months postoperatively.

Participants and materials

We identified 22 patients who were treated surgically for lower leg fractures and underwent soft tissue reconstruction via plastic surgery from January 2012 through December 2017 by querying the hospital database and using the International Classification of Disease (ICD) code for both fractures and flap procedures. To avoid including patients with improper codes and those who did not fulfill our inclusion criteria, all patient charts were screened manually. All variables that were to be recorded were specified in advance in a pre-prepared spreadsheet. Inclusion criteria were to be older than 18 years of age and to have sustained a traumatic open/closed lower leg fracture, localized as code 43 or 44 according to the AO/OTA classification (Arbeitsgemeinschaft für Osteosynthesefragen Foundation/Orthopaedic Trauma Association classification), primarily treated with bone stabilization and secondarily with one or more flaps for tissue reconstruction.

Descriptive and outcome measures

Standard parameters that we collected were age, sex and body mass index (BMI). Comorbidities were also recorded and categorized into four groups according to the number of comorbidities as follows: no comorbidity, 1–3 comorbidities, 4–5 comorbidities, and ≥ 6 comorbidities. Diabetes mellitus, nicotine abuse, and alcohol/drug abuse were listed separately as nominal scale variables. Accompanying injuries to the affected ankle joints were classified as closed or open fractures (open fractures with soft tissue damage were assigned a score > 1, as indicated by Gustilo and Anderson) [5]. Fracture morphology was classified according to the AO/OTA criteria [7]. Complications of osteosynthesis and flap coverage were reported. The results of preoperative vascular diagnostic tests, consisting of Duplex ultrasound of the venous system and interventional angiography of the arteries, were categorized as binary variables.

Postoperative outcomes were measured using two different patient-reported outcome scores: FAOS and its corresponding subscores – including symptoms, pain, function in daily living / activities of daily living (ADL), function in sports and recreational activities (sport/rec), and QoL – and the EQ-5D-5L score, a well-validated generic health-related QoL instrument [8] comprising the EQ-5D Index and the EQ-5D visual analog scale (VAS).

Regarding the FAOS score (maximum, 100), a lower score represented more symptoms or pain, greater difficulty performing ADL and sport/rec, and poorer QoL. This rating is also valid for the EQ-5D VAS (maximum, 100).

Statistical analysis

Findings are reported by the mean value for continuous data (standard deviation between parentheses) and number for categorical data (percentage between parentheses). T-tests for continuous variables and chi-square tests for categorical variables were performed when appropriate. All tests were two-sided, and statistical significance was set at p < 0.05. Analyses were performed using IBM SPSS Statistics version 24 software.

Results

Participants

We identified 22 patients according to our inclusion criteria. Eighteen patients returned the questionnaires. Of the four non-responders, one patient had died, one was not able to respond because of a mental disorder, and two were not interested in responding. All data concerning descriptive information on the patient sample are shown in Table 1. Moreover, results concerning occupational outcomes of surgery are the following. Before their trauma, 11.1% of patients were pensioners, 22.2% were unemployed, and 67.5% were employed. Of those who were employed, 37.5% returned to work. After returning to work, 50% of the patients had persistent symptoms
and 50% reported limitations at work due to their injuries.

Table 1
Descriptive data of the study cohort.

| Continuous variables | Mean | SD  | Range     |
|----------------------|------|-----|-----------|
| Age (years)          | 58.0 | 15.9| 17–81     |
| BMI (kg/m²)          | 27.6 | 6.5 | 19.1–42.5 |

| Categorical variables | N¹  | %    |
|-----------------------|-----|------|
| Sex                   |     |      |
| m                     | 14  | 63.6 |
| f                     |  8  | 36.4 |
| Smoking               |     |      |
| Y                     | 12  | 54.5 |
| N                     | 10  | 45.5 |
| Substance Abuse       |     |      |
| Y                     |  8  | 36.4 |

Fracture types and complications
Fractures were classified according to the AO/OTA classification and to the criteria by Gustilo and Anderson [5] (Table 2).
### Table 2

Classification of fractures.

| Classification AO/OTA | N\(^1\) | %  |
|-----------------------|---------|----|
| 44 A1                 | 3       | 13.6 |
| 44 A2                 | 2       | 9.1  |
| 44 A3                 | 1       | 4.5  |
| 44 B1                 | 3       | 13.6 |
| 44 B3                 | 5       | 22.7 |
| 44 C2                 | 1       | 4.5  |

All closed fractures developed necrosis and surgical site infection (SSI) and required subsequent revisions and debridement, which resulted in larger soft tissue defects. In 15 of 17 instances of SSI, bacterial contamination was detected (Table 3).

**Abbreviation:** E1 = Escherichia; E2 = Enterococcus; E3 = Enterobacter; N1 = number; N = no; SSI = surgical site infection; Staph = Staphylococcus; Strep = Streptococcus; Y = yes.
Preoperatively, interventional arteriography was performed in 16 patients and Duplex ultrasound of the venous system was performed in six of those 16 patients without findings of thrombosis. In seven patients, adequate circulation in all three arteries of the lower leg was found. In five patients, arterial stenosis was treated by balloon dilation. A venous bypass graft was applied in one patient. In three patients, treatment with angiography and recanalization via stenting of the occlusion was performed after loss of the first flap. Complications occurred in 12 flaps; in 10 of those cases, the flap was lost due to perfusion problems and necrosis and another flap coverage had to be provided. The mean number of revision surgeries was 7.63 ± 4.98 (range 2–22). None of our patients reported problems at the donor sites after soft tissue grafts in the form of wound healing disorders, pain or mobility limitations.

**Patient-reported outcomes**

The results of FAOS and EQ-5D are given in Table 4. Patients complained about in subscale “quality of life” with a score of 32.3 mostly. Symptoms were moderate and the patients were bothered of pain at least.

| Outcomes: FAOS, FAOS subscores, and EQ-5D VAS scores. |
|------------------------------------------------------|
| Mean | SD | Minimum | Maximum |
| FAOS | 60.7 | 22.2 | 27.00 | 100 |
| Symptoms | 60.1 | 27.5 | 21.43 | 100 |
| Pain | 73.6 | 23.0 | 30.56 | 100 |
| ADL | 66.9 | 19.7 | 38.24 | 100 |
| Sport/Rec | 40.4 | 39.1 | 0.0 | 100 |
| QoL | 32.3 | 28.8 | 0.0 | 100 |
| EQ-5D VAS | 57.7 | 20.2 | 30.00 | 100 |
| EQ-5D index | 0.6215 | 0.279 | 0.13 | 1 |

| Abbreviations: ADL = activities of daily living; FAOS = Foot and Ankle Outcome Score; QoL = quality of life; SD = standard deviation; Sport/Rec = function in sports and recreational activities; VAS = visual analog scale. |

Two patients with amputations were included in the follow-up. One of those two patients underwent bilateral amputation after 22 revision surgeries; he reported an EQ-5D VAS of 50 and an EQ-5D index of 0.26. The other patient experienced bilateral trauma and underwent direct amputation on one side and seven surgeries on the other side; he reported an EQ-5D VAS of 80 and an EQ-5D index of 0.91.

Furthermore, we analyzed the outcome of the 10 patients with flap ischemia in comparison with all the other patients. In our follow-up examinations we have determined that patients with flap ischemia had poorer outcomes than patients without ischemic complications. Detailed FAOS subscores and EQ-5D VAS related to ischemic and non-ischemic groups are shown in Table 5. Patients with ischemia were found to complain more in all subscores, especially in symptoms, sports and daily activities, but mostly in QoL, with a score of 21.88.
Table 5
Ischemia of flaps.

Discussion

This study aimed to show the course of treatment in a highly selective patient cohort with lower leg fractures treated with reconstruction and flap coverage. Furthermore, we aimed to detect postoperative complications and outcomes. For all 22 patients, complications such as SSI, necrosis, implant failure, the presence of an open fracture or other factors led to subsequent flap coverage. The bacterial spectrum described in this study is almost identical to that reported in national surveillance data [9].

The results of FAOS and EQ-5D index and VAS instruments in our study detected very poor function and QoL in patients who experienced lower leg fractures requiring flap coverage. Furthermore, patients with flap ischemia have shown the poorest outcomes in our cohort, as measured by FAOS, FAOS subscores, EQ-5D index and VAS.

Van Bergen et al. stated that the minimal detectable changes of each FAOS subscore were 17.1–20.8 at the individual level and 2.0–2.4 at group level in the validation of the German version of the FAOS [10]. In a recent review, the FAOS were shown to be reliable tools for the re-evaluation of ankle injuries and the assessment of their recovery [11]. Considering these data, it is possible to compare our FAOS scores with results from other studies. Duckworth et al. reported a mean FAOS score of 76 (mean follow-up 6 years) in complex tibial pilon fractures, compared with the score of 60.7 in our study (mean follow-up 41 months) [12]. Unfortunately, no subscores were reported. Kent et al. evaluated unstable syndesmotic injuries with different treatment options [13]. Among three subgroups, the group with the worst outcome had the following results in the subscores: pain (89), symptoms (75), ADL (97), sport/rec (75) and QoL (44). In their study with 1,670 patients with different ankle pathologies, despite comparable data, Golightly et al. have found a significantly better QoL (83 points).
In comparison to these studies, it can be confirmed that our patients had a particularly poor outcome. Two previous studies with different type of ankle fractures found that the EQ-5D VAS score and EQ-5D index were significantly higher than those we observed in our current study with a mean EQ-5D VAS of 57.6 (30–100) and a mean EQ-5D index of 0.621 (-0.205–1.000) [15, 16]. In our study, patients who required many revision surgeries were hospitalized for long periods because of limb salvage with a subsequent limited mobility, which may explain their measured QoL was poor. In a randomized study by Andersen et al. involving 97 patients with ankle injuries and follow-up at two years, much better EQ-5D VAS scores were reported, with a mean of 90 (75–95); however, none of these cases had any large soft tissue defects, so they didn’t need a flap coverage [15]. In our study, instead, each patient needed at least one flap coverage because of large soft tissue defects, which could explain why the scores of our cohort are lower than the scores of the cohort of Andersen et al. [15]. Coherently with previous findings, our study shows that severe injuries and complications determining multiple revisions and flap coverage have a negative impact on factors such as quality of life.

The Lower Extremity Assessment Project (LEAP) study examined patients up to 7 years postoperatively and indicated poor physical and psychosocial results after lower limb trauma regardless of the initial treatment options (amputation or reconstruction). Both patient groups were severely disabled compared to the overall population [1]. Return to work was possible for 37.5% of our patients at the mean follow-up period of 41.2 months (22 to 84); however, according to the LEAP study, the return to work rate was 58% at 7-year follow-up [17]. Therefore, it may be expected that the return to work rate could be higher in our patient group after 7 years. Patients who underwent limb salvaging required many surgeries, experienced complications such as bone and soft tissue infections, experienced disabilities, and required long hospitalizations. A meta-analysis revealed that limb reconstruction was at least as effective as amputation in terms of physical criteria such as the ability to perform ADL and of recovery time required before being able to return to work [18].

Despite having undergone similar surgeries for comparable complications and conditions, the scores of the two amputees in our study showed great discrepancies relative to the other participants. These results may reflect the subjective perception of postoperative daily routines and patient status. These two patients were not able to go back to their professional life. EQ-5D VAS scores of these two patients were reported as 50 vs 80.

By focusing on a specific cohort, our study highlighted the peculiarities that differentiate these patients from those that undergo surgeries with lower rates of complications. However, focusing on a restricted sample was also a source of limitations for our work, as more detailed subgroup analyses could not be carried out. Another limitation consisted in our study having a retrospective single-center design.

**Conclusion**

This study primarily aimed to evaluating postoperative outcomes in patients who required soft tissue reconstruction for lower leg fractures. Our results showed that worse QoL, ADL and other factors can be observed in patients undergoing several surgical revisions due to postoperative complications.

Furthermore, we showed that lower leg fractures with a subsequent flap coverage are the result of their complex injury and / or postoperative complications which require several surgical revisions. In particular, patients suffering from flap ischemia were shown to have worse outcomes Therefore, we recommend that preoperative angiography diagnostics should be implemented as part of standard diagnostic tests before treatment of the fractures and subsequent flaps.
