Abstract

We introduce new families of Integral Probability Metrics (IPM) for training Generative Adversarial Networks (GAN). Our IPMs are based on matching statistics of distributions embedded in a finite dimensional feature space. Mean and covariance feature matching IPMs allow for stable training of GANs, which we will call McGan. McGan minimizes a meaningful loss between distributions.

1. Introduction

Unsupervised learning of distributions is an important problem, in which we aim to learn underlying features that unveil the hidden structure in the data. The classic approach to learning distributions is by explicitly parametrizing the data likelihood and fitting this model by maximizing the likelihood of the real data. An alternative recent approach is to learn a generative model of the data without explicit parametrization of the likelihood. Variational Auto-Encoders (VAE) (Kingma & Welling, 2013) and Generative Adversarial Networks (GAN) (Goodfellow et al., 2014) fall under this category.

We focus on the GAN approach. In a nutshell GANs learn a generator of the data via a min-max game between the generator and a discriminator, which learns to distinguish between “real” and “fake” samples. In this work we focus on the objective function that is being minimized between the learned generator distribution \( P_\theta \) and the real data distribution \( P_r \).

The original work of (Goodfellow et al., 2014) showed that in GAN this objective is the Jensen-Shannon divergence. (Nowozin et al., 2016) showed that other \( \varphi \)-divergences can be successfully used. The Maximum Mean Discrepancy objective (MMD) for GAN training was proposed in (Li et al., 2015; Dziugaite et al., 2015). As shown empirically in (Salimans et al., 2016), one can train the GAN discriminator using the objective of (Goodfellow et al., 2014) while training the generator using mean feature matching. An energy based objective for GANs was also developed recently (Zhao et al., 2017). Finally, closely related to our paper, the recent work Wasserstein GAN (WGAN) of (Arjovsky et al., 2017) proposed to use the Earth Moving distance (EM) as an objective for training GANs. Furthermore (Arjovsky et al., 2017) show that the EM objective has many advantages as the loss function correlates with the quality of the generated samples and the mode dropping problem is reduced in WGAN.

In this paper, inspired by the MMD distance and the kernel mean embedding of distributions (Muandet et al., 2017) we propose to embed distributions in a finite dimensional feature space and to match them based on their mean and covariance feature statistics. Incorporating first and second order statistics has a better chance to capture the various modes of the distribution. While mean matching was empirically used in (Salimans et al., 2016), we show in this work that it is theoretically grounded: similarly to the EM distance in (Arjovsky et al., 2017), mean and covariance feature matching of two distributions can be written as a distance in the framework of Integral Probability Metrics (IPM) (Muller, 1997). To match the means, we can use any \( \ell_q \) norm, hence we refer to mean matching IPM as IPM\(_{\mu,q}\).

For matching covariances, in this paper we consider the nuclear norm and refer to the corresponding IPM as IPM\(_{\Sigma}\).

Our technical contributions can be summarized as follows:

a) We show in Section 3 that the \( \ell_q \) mean feature matching IPM\(_{\mu,q}\) has two equivalent primal and dual formulations and can be used as an objective for GAN training in both formulations.

b) We show in Section 3.3 that the parametrization used in Wasserstein GAN corresponds to \( \ell_1 \) mean feature matching GAN (IPM\(_{\mu,1}\) GAN in our framework).

c) We show in Section 4.2 that the covariance feature matching IPM\(_{\Sigma}\) admits also two dual formulations, and can be used as an objective for GAN training.

d) Similar to Wasserstein GAN, we show that mean feature matching and covariance matching GANs (McGan) are stable to train, have a reduced mode dropping and the IPM loss

correlates with the quality of the generated samples.

2. Integral Probability Metrics

We define in this Section IPMs as a distance between distributions. Intuitively each IPM finds a “critic” \( f \) (Arjovsky et al., 2017) which maximally discriminates between the distributions.

2.1. IPM Definition

Consider a compact space \( \mathcal{X} \) in \( \mathbb{R}^d \). Let \( \mathcal{F} \) be a set of measurable and bounded real valued functions on \( \mathcal{X} \). Let \( \mathcal{P}(\mathcal{X}) \) be the set of measurable probability distributions on \( \mathcal{X} \). Given two probability distributions \( P, Q \in \mathcal{P}(\mathcal{X}) \), the Integral probability metric (IPM) indexed by the function space \( \mathcal{F} \) is defined as follows (Muller, 1997):

\[
\|d_{\mathcal{F}}(P, Q)\| = \sup_{f \in \mathcal{F}} \left| \mathbb{E}_{x \sim P} f(x) - \mathbb{E}_{x \sim Q} f(x) \right|.
\]

In this paper we are interested in symmetric function spaces \( \mathcal{F} \), i.e. \( \forall f \in \mathcal{F}, -f \in \mathcal{F} \), hence we can write the IPM in that case without the absolute value:

\[
\|d_{\mathcal{F}}(P, Q)\| = \sup_{f \in \mathcal{F}} \left\{ \mathbb{E}_{x \sim P} f(x) - \mathbb{E}_{x \sim Q} f(x) \right\}.
\]

(1)

It is easy to see that \( d_{\mathcal{F}} \) defines a pseudo-metric over \( \mathcal{P}(\mathcal{X}) \). \( d_{\mathcal{F}} \) is non-negative, symmetric and satisfies the triangle inequality. A pseudo metric means that \( d_{\mathcal{F}}(P, P) = 0 \) but \( d_{\mathcal{F}}(P, Q) = 0 \) does not necessarily imply \( P = Q \).

By choosing \( \mathcal{F} \) appropriately (Sriperumbudur et al., 2012; 2009), various distances between probability measures can be defined. In the next subsection following (Arjovsky et al., 2017; Li et al., 2015; Dziugaite et al., 2015) we show how to use IPM to learn generative models of distributions, then we specify a special set of functions \( \mathcal{F} \) that makes the learning tractable.

2.2. Learning Generative Models with IPM

In order to learn a generative model of a distribution \( P_r \in \mathcal{P}(\mathcal{X}) \), we learn a function

\[
g_\theta : \mathcal{Z} \subset \mathbb{R}^{n_z} \rightarrow \mathcal{X},
\]

such that for \( z \sim p_z \), the distribution of \( g_\theta(z) \) is close to the real data distribution \( P_r \), where \( p_z \) is a fixed distribution on \( \mathcal{Z} \) (for instance \( z \sim \mathcal{N}(0, I_k) \)). Let \( P_\theta \) be the distribution of \( g_\theta(z) \), \( z \sim p_z \). Using an IPM indexed by a function class \( \mathcal{F} \) we shall solve therefore the following problem:

\[
\min_{g_\theta} d_{\mathcal{F}}(P_r, P_\theta)
\]

(2)

Hence this amounts to solving the following min-max problem:

\[
\min_{g_\theta} \sup_{f \in \mathcal{F}} \mathbb{E}_{x \sim P_r} f(x) - \mathbb{E}_{z \sim p_z} f(g_\theta(z))
\]

Given samples \( \{x_i, 1 \ldots N\} \) from \( P_r \) and samples \( \{z_i, 1 \ldots M\} \) from \( p_z \) we shall solve the following empirical problem:

\[
\min_{g_\theta} \sup_{f \in \mathcal{F}} \frac{1}{N} \sum_{i=1}^{N} f(x_i) - \frac{1}{M} \sum_{j=1}^{M} f(g_\theta(z_j))
\]

in the following we consider for simplicity \( M = N \).

3. Mean Feature Matching GAN

In this Section we introduce a class of functions \( \mathcal{F} \) having the form \( \langle v, \Phi_\omega(x) \rangle \), where vector \( v \in \mathbb{R}^m \) and \( \Phi_\omega : \mathcal{X} \rightarrow \mathbb{R}^m \) a non linear feature map (typically parametrized by a neural network). We show in this Section that the IPM defined by this function class corresponds to the distance between the mean of the distribution in the \( \Phi_\omega \) space.

3.1. IPM_{\mu,q}: Mean Matching IPM

More formally consider the following finite dimensional Hilbert space:

\[
\mathcal{F}_{v,\omega,p} = \{ f(x) = \langle v, \Phi_\omega(x) \rangle \mid v \in \mathbb{R}^m, \|v\|_p \leq 1, \Phi_\omega : \mathcal{X} \rightarrow \mathbb{R}^m, \omega \in \Omega \},
\]

where \( \|\cdot\|_p \) is the \( \ell_p \) norm. \( \mathcal{F}_{v,\omega,p} \) is the space of bounded linear functions defined in the non linear feature space induced by the parametric feature map \( \Phi_\omega \). \( \Phi_\omega \) is typically a multi-layer neural network. The parameter space \( \Omega \) is chosen so that the function space \( \mathcal{F} \) is bounded.

We recall here simple definitions on dual norms that will be necessary for the analysis in this Section. Let \( p, q \in [1, \infty] \), such that \( \frac{1}{p} + \frac{1}{q} = 1 \). By duality of norms we have:

\[
\|x\|_q = \max_{\|v\|_p \leq 1} \langle v, x \rangle \text{ and the Holder inequality: } \|x, y\| \leq \|x\|_p \|y\|_q.
\]

From Holder inequality we obtain the following bound:

\[
\|f(x)\| = \|\langle v, \Phi_\omega(x) \rangle\| \leq \|v\|_p \|\Phi_\omega(x)\|_q \leq \|\Phi_\omega(x)\|_q.
\]

To ensure that \( f \) is bounded, it is enough to consider \( \Omega \) such that \( \|\Phi_\omega(x)\|_q \leq B, \forall x \in \mathcal{X} \). Given that the space \( \mathcal{X} \) is bounded it is sufficient to control the norm of the weights and biases of the neural network \( \Phi_\omega \) by regularizing the \( \ell_\infty \) (clamping) or \( \ell_2 \) norms (weight decay) to ensure the boundedness of \( \mathcal{F}_{v,\omega,p} \).

Now that we ensured the boundedness of \( \mathcal{F}_{v,\omega,p} \), we look
We refer to formulations (3) and (4) as primal and dual formulations respectively.

The dual formulation in Equation (4) has a simple interpretation as an adversarial learning game: while the feature space $\Phi_\omega$ tries to map the mean feature embeddings of the real distribution $P_r$ and the fake distribution $P_\theta$ to be far apart (maximize the $\ell_q$ distance between the mean embeddings), the generator $g_\theta$ tries to put them close to one another. Hence we refer to this IPM as mean matching IPM.
We devise empirical estimates of both formulations in Equations (3) and (4), given samples \( \{x_i, i = 1 \ldots N \} \) from \( P_r \), and \( \{z_i, i = 1 \ldots N \} \) from \( p_z \). The primal formulation (3) is more amenable to stochastic gradient descent since the expectation operation appears in a linear way in the cost function of Equation (3), while it is non-linear in the cost function of the dual formulation (4) (inside the norm). We give here the empirical estimate of the primal formulation by giving empirical estimates \( L^\mu_p(v, \omega, \theta) \) of the primal cost function:

\[
(P_\mu) : \min_{g_\theta} \max_{v, \omega \in \Omega} \left\{ \frac{1}{N} \sum_{i=1}^{N} \Phi_\omega(x_i) - \frac{1}{N} \sum_{i=1}^{N} \Phi_\omega(g_\theta(z_i)) \right\}
\]

An empirical estimate of the dual formulation can be also given as follows:

\[
(D_\mu) : \min_{g_\theta} \max_{\omega \in \Omega} \left\| \frac{1}{N} \sum_{i=1}^{N} \Phi_\omega(x_i) - \frac{1}{N} \sum_{i=1}^{N} \Phi_\omega(g_\theta(z_i)) \right\|_q
\]

In what follows we refer to the problem given in \( (P_\mu) \) and \( (D_\mu) \) as \( \ell_q \) Mean Feature Matching GAN. Note that while \( (P_\mu) \) does not need real samples for optimizing the generator, \( (D_\mu) \) does need samples from real and fake. Furthermore we will need a large minibatch of real data in order to get a good estimate of the expectation. This makes the primal formulation more appealing computationally.

### 3.3. Related Work

We show in this section that several previous works on GAN, can be written within \( \ell_q \) mean feature matching IPM \( (IPM_{\mu, q}) \) minimization framework:

a) **Wasserstein GAN (WGAN):** (Arjovsky et al., 2017) recently introduced Wasserstein GAN. While the main motivation of this paper is to consider the IPM indexed by Lipschitz functions on \( \chi \), we show that the particular parametrization considered in (Arjovsky et al., 2017) corresponds to a mean feature matching IPM. Indeed (Arjovsky et al., 2017) consider the function set parametrized by a convolutional neural network with a linear output layer and weight clipping. Written in our notation, the last linear layer corresponds to \( v \), and the convolutional neural network below corresponds to \( \Phi_\omega \). Since \( v \) and \( \omega \) are simultaneously clamped, this corresponds to restricting \( v \) to be in the \( \ell_\infty \) unit ball, and to define in \( \Omega \) constraints on the \( \ell_\infty \) norms of \( \omega \). In other words (Arjovsky et al., 2017) consider functions in \( \mathcal{F}_{v,\omega,\theta} \), where \( p = \infty \). Setting \( p = \infty \) in Equation (3), and \( q = 1 \) in Equation (4), we see that in WGAN we are minimizing \( d_{\mathcal{F},\omega,\infty} \), that corresponds to \( \ell_1 \) mean feature matching GAN.

b) **MMD GAN:** Let \( \mathcal{H} \) be a Reproducing Kernel Hilbert Space (RKHS) with \( k \) its reproducing kernel. For any valid PSD kernel \( k \) there exists an \( \ell_2 \) mean and covariance feature matching IPM \( \Phi : \chi \rightarrow \mathcal{H} \) such that: \( k(x, y) = \langle \Phi(x), \Phi(y) \rangle_\mathcal{H} \). For an RKHS \( \Phi \) is noted usually \( k(x,.) \) and satisfies the reproducing property:

\[
f(x) = \langle f, \Phi(x) \rangle_\mathcal{H}, \text{ for all } f \in \mathcal{H}.
\]

Setting \( \mathcal{F} = \{ f \mid ||f||_\mathcal{H} \leq 1 \} \) in Equation (1) the IPM \( d_\mathcal{F} \) has a simple expression:

\[
d_\mathcal{F}(P, Q) = \sup_{f, ||f||_\mathcal{H} \leq 1} \left\{ \left\langle f, \mathbb{E}_{x \sim P} \Phi(x) - \mathbb{E}_{x \sim Q} \Phi(x) \right\rangle \right\} = \left\| \mu(P) - \mu(Q) \right\|_\mathcal{H}, \tag{5}
\]

where \( \mu(P) = \mathbb{E}_{x \sim P} \Phi(x) \in \mathcal{H} \) is the so called kernel mean embedding (Muandet et al., 2017). \( d_\mathcal{F} \) in this case is the so called Maximum kernel Mean Discrepancy (MMD) (Gretton et al., 2012). Using the reproducing property MMD has a closed form in term of the kernel \( k \). Note that IPM\( _{\mu, 2} \) is a special case of MMD when the feature map is finite dimensional, with the main difference that the feature map is fixed in case of MMD and learned in the case of IPM\( _{\mu, 2} \). (Li et al., 2015; Dziugaite et al., 2015) showed that GANs can be learned using MMD with a fixed gaussian kernel.

c) **Improved GAN:** Building on the pioneering work of (Goodfellow et al., 2014), (Salimans et al., 2016) suggested to learn the discriminator with the binary cross entropy criterion of GAN while learning the generator with \( \ell_2 \) mean feature matching. The main difference of our IPM\( _{\mu, 2} \) GAN is that both “discriminator” and “generator” are learned using the mean feature matching criterium, with additional constraints on \( \Phi_\omega \).

### 4. Covariance Feature Matching GAN

#### 4.1. IPM\( _{\Sigma} \): Covariance Matching IPM

As follows from our discussion of mean matching IPM comparing two distributions amounts to comparing a first order statistics, the mean of their feature embeddings. Here we ask the question how to incorporate second order statistics, i.e covariance information of feature embeddings.

In this Section we will provide a function space \( \mathcal{F} \) such that the IPM in Equation (1) captures second order information. Intuitively a distribution of points represented in a feature space can be approximately captured by its mean and its covariance. Commonly in unsupervised learning, this covariance is approximated by its first \( k \) principal components (PCA directions), which capture the directions of maximal variance in the data. Similarly, the metric we define in this Section will find \( k \) directions that maximize the discrimination between the two covariances. Adding second order information would enrich the discrimination power of the feature space (See Figure 1).
This intuition motivates the following function space of bilinear functions in $\Phi_\omega$:

$$\mathcal{F}_{U,V,\omega} = \{ f(x) = \sum_{j=1}^{k} \langle u_j, \Phi_\omega(x) \rangle \langle v_j, \Phi_\omega(x) \rangle \}$$

where $(u_j), (v_j) \in \mathbb{R}^{m}$ orthonormal $j = 1 \ldots k, \omega \in \Omega$.

Note that the set $\mathcal{F}_{U,V,\omega}$ is symmetric and hence the IPM indexed by this set (Equation (1)) is well defined. It is easy to see that $\mathcal{F}_{U,V,\omega}$ can be written as:

$$\mathcal{F}_{U,V,\omega} = \{ f(x) = \langle U^T \Phi_\omega(x), V^T \Phi_\omega(x) \rangle \}$$

$$U, V \in \mathbb{R}^{m \times k}, U^T U = I_k, V^T V = I_k, \omega \in \Omega$$

the parameter set $\Omega$ is such that the function space remains bounded. Let

$$\Sigma_\omega(P) = \mathbb{E}_{x \sim P} \Phi_\omega(x) \Phi_\omega(x)^T,$$

be the uncentered feature covariance embedding of $P$. It is easy to see that $\mathbb{E}_{x \sim P} f(x)$ can be written in terms of $U, V,$ and $\Sigma_\omega(P)$:

$$\mathbb{E}_{x \sim P} f(x) = \mathbb{E}_{x \sim P} \langle U^T \Phi_\omega(x), V^T \Phi_\omega(x) \rangle = \text{Trace}(U^T \Sigma_\omega(P) V).$$

For a matrix $A \in \mathbb{R}^{m \times m}$, we note by $\sigma_j(A)$ the singular value of $A$, $j = 1 \ldots m$ in descending order. The 1-schatten norm or the nuclear norm is defined as the sum of singular values, $\|A\|_\nu = \sum_{j=1}^{m} \sigma_j$. We note by $[A]_k$ the $k$th rank approximation of $A$. We note $\mathcal{O}_{m,k} = \{ M \in \mathbb{R}^{m \times k} \mid M^T M = I_k \}$. Consider the IPM induced by this function set. Let $P, Q \in \mathcal{P}(\mathcal{X})$ we have:

$$d_{\mathcal{F}_{U,V,\omega}}(P, Q) = \sup_{f \in \mathcal{F}_{U,V,\omega}} \mathbb{E}_{x \sim P} f(x) - \mathbb{E}_{x \sim Q} f(x)$$

$$= \max_{U \in \mathcal{O}_{m,k}} \mathbb{E}_{x \sim P} f(x) - \mathbb{E}_{x \sim Q} f(x)$$

$$= \max_{\omega \in \Omega} \max_{U \in \mathcal{O}_{m,k}} \text{Trace} \left[ U^T (\Sigma_\omega(P) - \Sigma_\omega(Q)) V \right]$$

$$= \max_{\omega \in \Omega} \sum_{j=1}^{k} \sigma_j(\Sigma_\omega(P) - \Sigma_\omega(Q))$$

$$= \max_{\omega \in \Omega} \| [\Sigma_\omega(P) - \Sigma_\omega(Q)]_k \|_\nu,$$

where we used the variational definition of singular values and the definition of the nuclear norm. Note that $U, V$ are the left and right singular vectors of $\Sigma_\omega(P) - \Sigma_\omega(Q)$. Hence $d_{\mathcal{F}_{U,V,\omega}}$ measures the worst case distance between the covariance feature embeddings of the two distributions, this distance is measured with the Ky Fan $k$-norm (nuclear norm of truncated covariance difference). Hence we call this IPM covariance matching IPM, IPM$_C$.

### 4.2. Covariance Matching GAN

Turning now to the problem of learning a generative model $g_\theta$ of $\mathcal{P}_r \in \mathcal{P}(\mathcal{X})$ using IPM$_C$ we shall solve:

$$\min_{g_\theta} d_{\mathcal{F}_{U,V,\omega}}(P_r, P_\theta),$$

this has the following primal formulation:

$$\min_{g_\theta} \max_{\omega \in \Omega} \mathcal{L}_\sigma(U, V, \omega, \theta),$$

where $\mathcal{L}_\sigma(U, V, \omega, \theta) = \mathbb{E}_{x \sim P_r} \langle U^T \Phi_\omega(x), V^T \Phi_\omega(x) \rangle - \mathbb{E}_{x \sim P_z} \langle U^T \Phi_\omega(g_\theta(z)), V^T \Phi_\omega(g_\theta(z)) \rangle,$

or equivalently the following dual formulation:

$$\min_{g_\theta} \max_{\omega \in \Omega} ||\Sigma_\omega(P_r) - \Sigma_\omega(P_\theta)||_k,$$

where $\Sigma_\omega(P_\theta) = \mathbb{E}_{z \sim P_z} \Phi_\omega(g_\theta(z)) \Phi_\omega(g_\theta(z))^T$.

The dual formulation in Equation (7) shows that learning generative models with IPM$_C$, consists in an adversarial game between the feature map and the generator, when the feature maps tries to maximize the distance between the feature covariance embeddings of the distributions, the generator tries to minimize this distance. Hence we call learning with IPM$_C$, covariance matching GAN.

We give here an empirical estimate of the primal formulation in Equation (6) which is amenable to stochastic gradient. The dual requires nuclear norm minimization and is more involved. Given $\{x_i, x_i \sim P_r\}$, and $\{z_j, z_j \sim P_z\}$, the covariance matching GAN can be written as follows:

$$\min_{g_\theta} \max_{\omega \in \Omega} \mathcal{L}_\sigma(U, V, \omega, \theta),$$

where $\mathcal{L}_\sigma(U, V, \omega, \theta) = \frac{1}{N} \sum_{i=1}^{N} \langle U^T \Phi_\omega(x_i), V^T \Phi_\omega(x_i) \rangle - \frac{1}{N} \sum_{j=1}^{N} \langle U^T \Phi_\omega(g_\theta(z_j)), V^T \Phi_\omega(g_\theta(z_j)) \rangle.$

### 4.3. Mean and Covariance Matching GAN

In order to match first and second order statistics we propose the following simple extension:

$$\min_{g_\theta} \max_{\omega \in \Omega} \mathcal{L}_\mu(v, \omega, \theta) + \mathcal{L}_\sigma(U, V, \omega, \theta),$$

that has a simple dual adversarial game interpretation

$$\min_{g_\theta} \max_{\omega \in \Omega} ||\mu_\omega(P) - \mu_\omega(P_\theta)||_q + ||\Sigma_\omega(P_r) - \Sigma_\omega(P_\theta)||_k,$$

where the discriminator finds a feature space that discriminates between means and variances of real and fake, and the generator tries to match the real statistics. We can also give empirical estimates of the primal formulation similar to expressions given in the paper.
5. Algorithms

We present in this section our algorithms for mean and covariance feature matching GAN (McGan) with IPM_µ,q and IPM_Σ.

**Mean Matching GAN.** Primal P_P: We give in Algorithm 1 an algorithm for solving the primal IPM_µ,q GAN (P_P). Algorithm 1 is adapted from (Arjovsky et al., 2017) and corresponds to their algorithm for p = ∞. The main difference is that we allow projection of v on different ℓ_p balls, and we maintain the clipping of ω to ensure boundedness of Φω. For example for p = 2, \( \text{proj}_{B_2^o}(v) = \min(1, \frac{1}{\|v\|_2^2})v \).

For p = ∞ we obtain the same clipping in (Arjovsky et al., 2017) \( \text{proj}_{B_∞^o}(v) = \text{clip}(v, -c, c) \) for c = 1.

Dual D_P: We give in Algorithm 2 an algorithm for solving the dual formulation IPM_µ,q GAN (D_P). As mentioned earlier we need samples from "real" and "fake" for training both generator and the "critic" feature space.

**Covariance Matching GAN.** Primal P_Σ: We give in Algorithm 3 an algorithm for solving the primal of IPM_Σ GAN (Equation (8)). The algorithm performs a stochastic gradient ascent on (ω, U, V) and a descent on θ. We maintain clipping on ω to ensure boundedness of Φω, and perform a QR retraction on the Stiefel manifold O_m,k (Abisol et al., 2007), maintaining orthonormality of U and V.

**Algorithm 1 Mean Matching GAN - Primal (P_P)**

**Input:** p to define the ball of v • q Learning rate, n_c number of iterations for training the critic, c clipping or weight decay parameter, N batch size

**Initialize v, ω, θ

repeat

for j = 1 to n_c do

Sample a minibatch \( x_i, i = 1 \ldots N, x_i \sim \mathbb{P}_r \)

Sample a minibatch \( z_i, i = 1 \ldots N, z_i \sim p_z \)

\( g_v, g_ω \leftarrow (\nabla_v \mathcal{L}_m(v, ω, θ), \nabla_ω \mathcal{L}_m(v, ω, θ)) \)

\( v, ω \leftarrow \text{RMSProp}((v, ω), (g_v, g_ω)) \)

\{Project v on ℓ_p ball, \( B_p = \{x, \|x\|_p \leq 1\} \}

\( v \leftarrow \text{proj}_{B_p}(v) \)

\( ω \leftarrow \text{clip}(ω, -c, c) \) \{Ensure Φω is bounded\}

end for

Sample \( z_i, i = 1 \ldots N, z_i \sim p_z \)

\( d_θ \leftarrow -\nabla_θ \left\langle v, \nabla_ω \sum_{i=1}^N \Phi_ω(g_ω(z_i)) \right\rangle \)

\( θ \leftarrow θ - q \text{ RMSProp}(θ, d_θ) \)

until θ converges

**Algorithm 2 Mean Matching GAN - Dual (D_P)**

**Input:** q the matching \( ℓ_q \) norm, \( η \) Learning rate, n_c number of iterations for training the critic, c clipping or weight decay parameter, N batch size

**Initialize v, ω, θ

repeat

for j = 1 to n_c do

Sample a minibatch \( x_i, i = 1 \ldots N, x_i \sim \mathbb{P}_r \)

Sample a minibatch \( z_i, i = 1 \ldots N, z_i \sim p_z \)

\( g_ω \leftarrow (\text{RMSProp}(ω, g_ω)) \)

\( ω \leftarrow ω + q \text{ RMSProp}(ω, g_ω) \)

\( ω \leftarrow \text{clip}(ω, -c, c) \) \{Ensure Φω is bounded\}

end for

Sample \( z_i, i = 1 \ldots N, z_i \sim p_z \)

\( d_θ \leftarrow -\nabla_θ \left\langle U \Phi_ω(g_ω(z_j)), V \Phi_ω(g_ω(z_j)) \right\rangle \)

\( θ \leftarrow θ - η \text{ RMSProp}(θ, d_θ) \)

until θ converges

**Algorithm 3 Covariance Matching GAN - Primal (P_Σ)**

**Input:** k the number of components, \( η \) Learning rate, n_c number of iterations for training the critic, c clipping or weight decay parameter, N batch size

**Initialize U, V, ω, θ

repeat

for j = 1 to n_c do

Sample a minibatch \( x_i, i = 1 \ldots N, x_i \sim \mathbb{P}_r \)

Sample a minibatch \( z_i, i = 1 \ldots N, z_i \sim p_z \)

\( G \leftarrow (\nabla_U, \nabla_V, \nabla_ω) \mathcal{L}_σ(U, V, ω, θ) \)

\( (U, V, ω) \leftarrow (U, V, ω) + q \text{ RMSProp}((U, V, ω), G) \)

\{Project U and V on the Stiefel manifold O_m,k \}

\( Q_u, R_u \leftarrow QR(U) \)

\( s_u \leftarrow \text{sign}(\text{diag}(R_u)) \)

\( Q_v, R_v \leftarrow QR(V) \)

\( s_v \leftarrow \text{sign}(\text{diag}(R_v)) \)

\( U \leftarrow Q_u \text{Diag}(s_u) \)

until θ converges

6. Experiments

We train McGan for image generation with both Mean Matching and Covariance Matching objectives. We show generated images on the labeled faces in the wild (LFW) (Huang et al., 2007), LSUN bedrooms (Yu et al., 2015), and cifar-10 (Krizhevsky & Hinton, 2009) datasets.

It is well-established that evaluating generative models is hard (Theis et al., 2016). Many GAN papers rely on a combination of samples for quality evaluation, supplemented by a number of heuristic quantitative measures. We will mostly focus on training stability by showing plots of the
loss function, and will provide generated samples to claim comparable sample quality between methods, but we will avoid claiming better sample quality. These samples are all generated at random and are not cherry-picked.

The design of $g_\theta$ and $\Phi_\omega$ are following DCGAN principles (Radford et al., 2015), with both $g_\theta$ and $\Phi_\omega$ being a convolutional network with batch normalization (Ioffe & Szegedy, 2015) and ReLU activations. $\Phi_\omega$ has output size $bs \times F \times 4 \times 4$. The inner product can then equivalently be implemented as $\text{conv}(4 \times 4, F \rightarrow 1)$ or $\text{flatten + Linear}(4 \times 4 \times F \rightarrow 1)$. We generate $64 \times 64$ images for lfw and LSUN and $32 \times 32$ images on cifar, and train with minibatches of size 64. We follow the experimental framework and implementation of (Arjovsky et al., 2017), where we ensure the boundedness of $\Phi_\omega$ by clipping the weights pointwise to the range $[-0.01, 0.01]$.

**Primal versus dual form of mean matching.** We trained mean matching GANs both in the primal and dual form, see respectively Algorithm 1 and 2. Samples are shown in Figure 2. The primal formulation of IPM$_{\mu,1}$ GAN corresponds to clipping $v$, i.e. the original WGAN, while for IPM$_{\mu,2}$ we divide $v$ by its $\ell_2$ norm if it becomes larger than 1. In the dual formulation, for $q = 2$ we noticed little difference between maximizing the $\ell_2$ norm or its square.

We observed that the default learning rates from WGAN (5e-5) are optimal for both primal and dual formulation. Figure 3 shows the loss (i.e. IPM estimate) dropping steadily for both the primal and dual formulation independently of the choice of the $\ell_q$ norm. We also observed that during the whole training process, samples generated from the same noise vector across iterations, remain similar in nature (face identity, bedroom style), while details and background will evolve. This qualitative observation indicates valuable stability of the training process.

For the dual formulation (Algorithm 2), we confirmed the hypothesis that we need a good estimate of $\mu_\omega(\mathbb{P}_r)$ in order to compute the gradient of the generator $\nabla_\theta$: we needed to increase the minibatch size of real threefold to $3 \times 64$.

**Covariance GAN.** We now experimentally investigate the IPM defined by covariance matching. For this section and the following, we use only the primal formulation, i.e. with explicit $u_j$ and $v_j$ orthonormal (Algorithm 3). Figure 4 and 5 show samples and loss from lfw and LSUN training respectively. We use Algorithm 3 with $k = 16$ components. We obtain samples of comparable quality to the mean matching formulations (Figure 2), and we found training to be stable independent of hyperparameters like number of components $k$ varying between 4 and 64.

**Covariance GAN with labels and conditioning.** Finally, we conduct experiments on the cifar-10 dataset, where we will leverage the additional label information by training...
a conditional GAN (Mirza & Osindero, 2014). The way we incorporate label information is following InfoGAN (Chen et al., 2016) and AC-GAN (Odena et al., 2016), where both real and generated data are labeled, but the label is not given as input to the discriminator. The generator sees the label by appending a one-hot encoding along the feature map dimension, i.e. the generator receives an input vector of size $(n_z + 10) \times 1 \times 1$. The classifier is a linear output layer $S$ on top of $\Phi_\omega$, followed by softmax. We now optimize a combination of the original IPM loss in the primal formulation with the cross-entropy loss $CE = -\mathbb{E}_{x,y} \log\text{softmax}(\langle S_y, \Phi_\omega(x) \rangle)$.

During the $n_c$ critic training iterations, we alternate between maximizing

- the IPM $\mathcal{L}_\sigma$ alone, where $g_{\theta}$ gets conditioning labels at random, and
- $\mathcal{L}_\sigma - \lambda_D CE$, where $g_{\theta}$ gets conditioning labels matching the real labels.

The generator is trained by sampling with random labels $y$ and always minimizes $\mathcal{L}_\sigma + \lambda_G CE$.

Results are shown in figure 6. Notice rows corresponding to recognizable classes, while the noise $z$ (shared within each column) clearly determines other elements of the visual style like dominant color, across label conditioning. Additional experimental results, with combinations of Mean and Covariance Matching are presented in the supplementary material.

7. Discussion

We noticed the influence of clipping on the capacity of the critic: a higher number of feature maps was needed to compensate for clipping. The question remains what alternatives to clipping of $\Phi_\omega$ can ensure the boundedness. For example, we successfully used an $\ell_2$ penalty on the weights of $\Phi_\omega$. Other directions are to explore geodesic distances between the covariances (Arsigny et al., 2006), and extensions of the IPM framework to the multimodal setting (Isola et al., 2016).

A. Subspace Matching Interpretation of Covariance Matching GAN

Let $\Delta_\omega = \Sigma_\omega(P) - \Sigma_\omega(Q)$. $\Delta_\omega$ is a symmetric matrix but not PSD, which has the property that its eigenvalues $\lambda_j$ are related to its singular values as given by: $\sigma_j = |\lambda_j|$ and its left and right singular vectors coincides with its eigenvectors and satisfy the following equality $u_j = \text{sign}(\lambda_j)v_j$. One can ask here if we can avoid having both $U, V$ in the definition of IPM since at the optimum $u_j = \pm v_j$. One could consider $\delta E_\omega(P_r, P_\theta)$ defined as follows:

$$\max_{\omega \in \Omega, U \in O_{m,k}} \mathbb{E}_{x \sim P_r} \|U\Phi_\omega(x)\|^2 - \mathbb{E}_{z \sim p_z} \|U\Phi_\omega(g_\theta(z))\|^2,$$

and then solve for $\min_{g_\theta} \delta E_\omega(P_r, P_\theta)$. Note that:

$$\delta E_\omega(P_r, P_\theta) = \max_{\omega \in \Omega, U \in O_{m,k}} \text{Trace}(U^T(\Sigma_\omega(P_r) - \Sigma_\omega(P_\theta)))U$$

$$= \max_{\omega \in \Omega} \sum_{i=1}^k \lambda_i(\Delta_\omega)$$

$\delta E_\omega$ is not symmetric furthermore the sum of those eigenvalues is not guaranteed to be positive and hence $\delta E_\omega$ is not guaranteed to be non negative, and hence does not define an IPM. Noting that $\sigma_i(\Delta_\omega) = |\lambda_i(\Delta_\omega)|$, we have that:

$$\text{IPM}_\Sigma(P_r, P_\theta) = \sum_{i=1}^k \sigma_i(\Delta_\omega) \geq \sum_{i=1}^k \lambda_i(\Delta_\omega) = \delta E_\omega(P_r, P_\theta).$$

Hence $\delta E$ is not an IPM but can be optimized as a lower bound of the IPM$_\Sigma$. This would have an energy interpretation as in the energy based GAN introduced recently (Zhao et al., 2017): the discriminator defines a subspace that has higher energy on real data than fake data, and the generator maximizes his energy in this subspace.

B. Mean and Covariance Matching Loss Combinations

We report below samples for McGan, with different IPM$_\mu, q$ and IPM$_\Sigma$ combinations. All results are reported for the same architecture choice for generator and discriminator, which produced qualitatively good samples with IPM$_\Sigma$ (Same one reported in Section 6 in the main paper). Note that in Figure 7 with the same hyper-parameters and architecture choice, WGAN failed to produce good sample. In other configurations training converged.
Figure 7. Cifar-10: Class-conditioned generated samples with $\text{IPM}_{\mu,1}(\text{WGAN})$. Within each column, the random noise $z$ is shared, while within the rows the GAN is conditioned on the same class: from top to bottom airplane, automobile, bird, cat, deer, dog, frog, horse, ship, truck.
Figure 8. Cifar-10: Class-conditioned generated samples with IPM$\mu, \Sigma$. Within each column, the random noise $z$ is shared, while within the rows the GAN is conditioned on the same class: from top to bottom airplane, automobile, bird, cat, deer, dog, frog, horse, ship, truck.
Figure 9. Cifar-10: Class-conditioned generated samples with IPM$\Sigma$. Within each column, the random noise $z$ is shared, while within the rows the GAN is conditioned on the same class: from top to bottom airplane, automobile, bird, cat, deer, dog, frog, horse, ship, truck.
Figure 10. Cifar-10: Class-conditioned generated samples with $\text{IPM}_{\mu, 1} + \text{IPM}_\Sigma$. Within each column, the random noise $z$ is shared, while within the rows the GAN is conditioned on the same class: from top to bottom airplane, automobile, bird, cat, deer, dog, frog, horse, ship, truck.
Figure 11. Cifar-10: Class-conditioned generated samples with IPM_{\mu, \Sigma} + IPM_{\Sigma}. Within each column, the random noise $z$ is shared, while within the rows the GAN is conditioned on the same class: from top to bottom airplane, automobile, bird, cat, deer, dog, frog, horse, ship, truck.
