Comparison of livestock-associated and community-associated *Staphylococcus aureus* pathogenicity in a mouse model of skin and soft tissue infection

Pranay R. Randad, Carly A. Dillen, Roger V. Ortines, David Mohr, Maliha Aziz, Lance B. Price, Hülya Kaya, Jesper Larsen, Karen C. Carroll, Tara C. Smith, Lloyd S. Miller & Christopher D. Heaney

Industrial hog operation (IHO) workers are at increased risk of carrying *Staphylococcus aureus* in their nares, particularly strains that are livestock-associated (LA) and multidrug-resistant. The pathogenicity of LA-*S. aureus* strains remains unclear, with some prior studies suggesting reduced transmission and virulence in humans compared to community-associated methicillin-resistant (CA-MRSA) *S. aureus*. The objective of this study was to determine the degree to which LA-*S. aureus* strains contracted by IHO workers cause disease relative to a representative CA-MRSA strain in a mouse model of skin and soft tissue infection (SSTI). Mice infected with CC398 LA-*S. aureus* strains (IHW398-1 and IHW398-2) developed larger lesion sizes with higher bacterial burden than mice infected with CA-MRSA (SF8300) (p < 0.05). The greatest lesion size and bacterial burden was seen with a CC398 strain that produced a recurrent SSTI in an IHO worker. The LA-*S. aureus* infected mice had decreased IL-1β protein levels compared with CA-MRSA-infected mice (p < 0.05), suggesting a suboptimal host response to LA-*S. aureus* SSTIs. WGS revealed heterogeneity in virulence factor and antimicrobial resistance genes carried by LA-*S. aureus* and CA-MRSA strains. The observed pathogenicity suggest that more attention should be placed on preventing the spread of LA-*S. aureus* into human populations.

In the past decade it has become evident that animal-adapted multidrug resistant *Staphylococcus aureus* (MDRSA) has emerged among food animals raised in concentrated animal feeding operations (CAFOs) and individuals who have frequent contact with food animals raised in CAFOs globally. A study conducted in Pennsylvania concluded that residential proximity to swine CAFO manure land application crop fields was associated with increased odds of methicillin-resistant *S. aureus* (MRSA) infection and skin and soft tissue infection (SSTI), suggesting an environmental exposure pathway wherein community members could become infected with antimicrobial-resistant *S. aureus* originating at swine CAFOs. This is consistent with evidence suggesting that industrial hog operation (IHO) workers are at an increased risk of carrying...
In the late 1990’s, and has become the dominant CA-MRSA strain circulating in North America. Consistent with its ability to cause severe and widespread disease, USA300, displayed considerably increased virulence in a mouse model of skin and soft tissue infection (SSTI) compared to other MRSA lineages.

At a genetic level, LA- S. aureus tend to lack genetic factors associated with human infection that are typically found in CA-MRSA lineages, including the human immune evasion cluster (IEC) genes (scn) and Panton-Valentine leukocidin (PVL)-encoding genes ( lukS-PV and lukF-PV). Nevertheless, LA- S. aureus strains have been reported to produce skin and bloodstream infections in humans in Europe and the USA, Canada, and China. A recent study concluded that a LA-MRSA isolate collected from poultry displayed greater lethality in a murine sepsis model compared to a clinical methicillin-susceptible S. aureus (MSSA) isolate and provided information on differential gene expression. To our knowledge, no studies have assessed the relative pathogenesis of LA- S. aureus acquired from swine on an IHO compared to a well-characterized and highly pathogenic CA-MRSA strain isolated from a human SSTI outbreak in the community. Considering that LA- S. aureus has surfaced in community members, including children, who experience environmental exposure to CAFOs, it is critical to improve our understanding of the pathogenic potential of LA- S. aureus strains emerging from CAFO environments and resulting in human SSTI. This study aims to understand the degree to which LA- S. aureus strains contracted by IHO workers cause disease relative to a representative hypervirulent CA-MRSA strain—i.e., USA300, which responsible for the vast majority of CA-MRSA SSTI in the USA, Canada, and Europe, and displays a high degree of pathogenicity in a mouse model of SSTI. Hemolytic activity was treated as a binary variable and was confirmed for each isolate by observation of a zone of hemolysis after 24-hours of growth on sheep blood agar plates.

Method Selection of S. aureus isolates. One CC9 and one CC8 LA-MRSA strain were selected that were collected from the anterior nares of two IHO workers who reported a SSTI within the past 3 months between October 2013 and February 2014 in a prospective cohort study of IHO workers in North Carolina (NCHW9 and NCHW8). Two CC398 LA-MRSA isolates were selected that were collected directly from two IHO workers' active skin infections between May 2011 and February 2013 in a prospective cohort study of IHO workers in Iowa, and were provided by Dr. Tara C. Smith from Kent State University (IHW398-1 and IHW398-2). IHW398-1 was responsible for a physician-diagnosed recurrent SSTI in a male hog worker. The representative CA-MRSA strain SF8300 was isolated from a SSTI in a patient treated at the San Francisco General Hospital and was provided by Dr. Henry Chambers of University of California San Francisco. SF8300 is pulsed-field type USA300, which responsible for the vast majority of CA-MRSA SSTI in the USA, Canada, and Europe, and displays a high degree of pathogenicity in a mouse model of SSTI. Hemolytic activity was treated as a binary variable and was confirmed for each isolate by observation of a zone of hemolysis after 24-hours of growth on sheep blood agar plates.

Antimicrobial susceptibility testing. Each selected S. aureus strain was subjected to a panel of antibiotics for antibiotic susceptibility testing (AST) using the Phoenix Automated Microbiology System (BD Diagnostic Systems, Sparks, MD) by the Clinical Microbiology Laboratory at the Johns Hopkins Hospital, according to guidelines for clinical isolates. MRSA was defined as resistant to cefoxitin or oxacillin and positive for the meca or meCC gene. MDRSA was defined as resistant to greater than or equal to three classes of antibiotics. MIC cut off’s used to establish resistant, intermediate, or susceptible phenotypes, and antibiotic abbreviations, are provided in Chapter 3: Supplementary Information (Table S1).

Mouse model of S. aureus skin and soft tissue infection. Animal care and all experiments were approved and performed in accordance with the guidelines and regulations approved by the Johns Hopkins University Animal Care and Use Committee, which conform to the Guide for the Care and Use of Laboratory Animals published by the US National Institutes of Health (8th edition, 2011). As a first step toward identifying the relative pathogenicity of LA- S. aureus compared to that of CA-MRSA, we evaluated the skin lesions that developed in response to intradermal (i.d.) infection of four LA-MDRSA isolates collected from IHO workers and...
libraries constructed from 500 ng input DNA. Uniquely barcoded adaptors used in adaptor ligation were obtained from BioO Scientific® (BioO Scientific®, Austin, TX, NEB, NEXTflex-96™ DNA Barcodes for DNA). Following Covaris, genomic DNA was fragmented to an average fragment size of 300 bp in 50 µL PBS of midlogarithmic growth phase SF8300 (CC8) (n = 20 mice) or the following LA-S. aureus strains (n = 10 mice/strain) NCHW8 (CC8), NCHW9 (CC9), IHW398-1 (CC398), or IHW398-2 (CC398). Digital photographs of mice taken on days 0, 1, 3, 7, 10, and 14 and analyzed for measurements of total lesion size (cm²) using ImageJ software. Data reported as mean total lesion size (cm²) ± the standard error of the mean (SEM).

**Measuring bacterial burden.** Mice (n = 5/group) were euthanized on day 3 post-infection and 10-mm skin punch biopsies of lesions were homogenized (Pro200 Series homogenizer; Pro Scientific, Oxford, CT) in PBS on ice. Samples were serially-diluted and cultured on TSA plates overnight and CFU were enumerated.

**Cytokine, chemokine, and growth factor evaluation in infected skin.** Infected skin biopsies from day 3 were analyzed for protein levels of cytokines, chemokines and growth factors to provide insights into the host response to CA-MRSA or LA-S. aureus i.d. inoculation. Mice (n = 5/group) were euthanized on day 3 post-infection and 10-mm skin punch biopsies of lesions were weighed and snap-frozen in liquid nitrogen. On ice, each specimen was homogenized with a hand-held homogenizer (Pro200 Series homogenizer; Pro Scientific) in Protein Lysis Buffer (Promega) containing protease inhibitor cocktail (Roche). All samples were stored at 80°C. Samples were then centrifuged at 4°C and supernatants were assayed for protein levels of cytokines, chemokines and growth factors using a 9-plex and 11-plex mouse protein array, according to the manufacturer’s recommendations (Bio-Plex Pro™, Biorad; Hercules, CA). For the 9-plex and 11-plex arrays, samples were normalized to 0.75 mg/mL and 2 mg/mL total protein, respectively. Samples were also assayed for myeloperoxidase (MPO) levels using a commercially available ELISA kit (R&D Systems, Minneapolis, MN).

**Genome sequencing.** We sequenced and assembled the genomes of the LA-MDRSA isolates, and used the publicly available genomic sequence of SF8300™ for WGS. DNA was prepared for multiplexed, paired-end sequencing on an Illumina MiSeq (Illumina, Inc., San Diego, CA). For each isolate, 500 ng of DNA was sheared to an average fragment size of 300 bp in 50 µL using a Covaris E220 Focused-Ultrasonicator (Covaris, Woburn, MA). End repair, A-tailing, and adaptor ligation of the total volume of sheared DNA was performed using the Kapa Hyper Prep Kit (Kapa Biosystems, Inc., Wilmington, MA) with recommended adaptor concentrations for libraries constructed from 500 ng input DNA. Uniquely barcoded adaptors used in adaptor ligation were obtained from BioO Scientific® (BioO Scientific®, Austin, TX, NEB, NEXTflex-96™ DNA Barcodes for DNA). Following ligation of adaptors, KAPA Pure Beads (Kapa Biosystems, Inc., Wilmington, MA) were used to perform a 0.8X bead-based cleanup for each DNA library. Individual libraries were quantified in triplicate at two concentrations (1:100 and 1:1000) via quantitative PCR using the Kapa Library Quantification kit (Kapa Biosystems, Inc. Wilmington, MA.). Based on individual library concentrations, equimolar pools of S. aureus libraries were prepared at a concentration of at least 1 nM. The pooled libraries were qcd on an Agilent bioanalyzer and sequenced on an Illumina MiSeq at 2 × 300 bp.

**De novo assembly and molecular characterization of S. aureus genomes.** To gain information on the genetic basis for the pathogenic potential of LA-MDRSA as compared to SF8300, we assessed the presence of core and mobile genetic element (MGE) encoded virulence factors (VF’s) and acquired antimicrobial resistance (AMR) genes important for pathogenesis in humans. Illumina short-read sequences were trimmed using
trimmomatic31, and assembled into contigs using the SPADES assembler (v.3.5)32. Assembly quality was assessed using QUAST (v.2.3)33, and reference MLST housekeeping genes were identified using BLAST (Version 2.2.25 +)34 at 100% query coverage and nucleotide identity (ID). An in-house script was used to match genes and MLST profile data35 to determine the final MLST type. These analyses were performed on the GWU Colonial High Performance Computing Cluster. Virulence factor (VF) and Antimicrobial resistance (AMR) genes were determined by uploading each assembled S. aureus genome onto the S. aureus VirulenceFinder 1.536 and ResFinder 3.037, available on the Center for Genomic Epidemiology (CGE) server. ABRicate (https://github.com/tseemann/abricate), a modified BLASTn based tool for the screening of genes in assemblies, was used with a custom database containing microbial surface components recognizing adhesive matrix molecules (MSCRAMMs), and several additional hemolysins and leucocidins, to detect the following genes on the assembled S. aureus genomes: clfA (GenBank accession no. Z18852) and clfB (GenBank accession no. AJ224764) encoding clumping factor A and B (ClfA and ClfB), sdrC (GenBank accession no. AJ005645), sdrD (GenBank accession no. AJ005646), and sdrE (GenBank accession no. AJ005647) encoding serine-aspartate repeat protein C, D, and E (SdrC, SdrD, and SdrE), bbp (GenBank accession no. BX571856) encoding bone sialoprotein-binding protein (Bbp), fnbpA (GenBank accession no. J04151) and fnbpB (GenBank accession no. X62992) encoding Fibrinogen-binding protein A and B (FnBPA and FnBPB), and cna (GenBank accession no. M81736) encoding collagen adhesin (Cna), hla (GenBank accession no. CP0000255, BX571856, BX571857, BA000017, BA000033, BA000018, CP000046) encoding for alpha hemolysin, hlb (GenBank accession no. BX571856, BX571857, BA000017, BA000033, BA000018, CP000046) encoding for beta hemolysin, lukA and lukB (GenBank accession no. AP009351) encoding for the LukAB leucocidin, and nor (GenBank accession no. BX571856) encoding for nitric oxide reductase. For all genome hits, the threshold of ID was set to 85% and percentage of minimum gene length was set to 60%. All genome hits were manually inspected for confirmation.

Statistical analysis. Data were compared using Student’s t test (two-tailed), comparing each LA-S. aureus strain to the representative SF8300 CA-MRSA referent strain. p-values < 0.05 were considered statistically significantly.

Results
LA-S. aureus and antibiotic susceptibility testing. Of the 17 antibiotics tested, complete or intermediate resistance was observed to all antibiotics except for vancomycin, linezolid, daptomycin, rifampicin, and nitrofurantoin (Fig. 1). All S. aureus clones were resistant to ampicillin and penicillin, and displayed a multidrug resistant phenotype, while only the CA-MRSA clone SF8300 displayed a methicillin-resistant phenotype (Fig. 1). The SF8300 isolate also displayed complete resistance to erythromycin and cefoxatine, and intermediate resistance to quinupristin/dalfopristin (Fig. 1). The NCHW8 isolate, collected from an IHO worker’s nares, additionally displayed resistance to erythromycin, clindamycin, and gentamycin (Fig. 1). Both CC398 isolates displayed resistance to tetracycline and intermediate resistance to quinupristin/dalfopristin and minocycline, while the IHV398-1 isolate, responsible for a recurrent SSTI in an IHO worker, also displayed resistance to moxifloxacin and sulfamethoxazole/trimethoprim (Fig. 1). The SSTI-associated CC9 isolate displayed resistance to erythromycin, clindamycin, and moxifloxacin (Fig. 1).
LA-S. aureus-infected mice and skin lesion size. Growth curves showed a mid-logarithmic phase at 3 hours for all isolates, and there were no statistically significant differences in growth curves between isolates (Fig. 2M.1). Mice were inoculated i.d. with $3 \times 10^7$ CFUs of mid-logarithmic growth phase S. aureus and skin lesion sizes were evaluated over time (Fig. 2A). All of the S. aureus strains resulted in visible skin lesions that healed by day 14. SF8300 and NCHW9 infected mice developed maximum lesion size on day 7 of $0.9 \pm 0.1 \text{ cm}^2$ and $0.8 \pm 0.1 \text{ cm}^2$, respectively. IHW398-1, IHW398-2, and NCHW8 infected mice developed maximum lesion sizes on day 3 of $1.3 \pm 0.1 \text{ cm}^2$, $1.0 \pm 0.1 \text{ cm}^2$, and $0.9 \pm 0.2 \text{ cm}^2$, respectively. Both CC398 LA-MRSA strains collected directly from IHO workers with active SSTI developed significantly larger lesion sizes on day 3 compared with SF8300 ($p < 0.05$) (Fig. 2B). The skin lesions sizes of all other LA-MRSA isolates (CC9 or CC8) were not statistically different from those of SF8300 at any time point. Of note, mice infected with the IHW398-1 clone which was responsible for a recurrent SSTI in an IHO worker, developed the largest lesion sizes, peaking on day 3 and were 2-fold greater than those of SF8300-infected mice (Fig. 2C).

LA-S. aureus-infected mice and bacterial burden. Given that the CC398 lesion sizes peaked on day 3, we evaluated the bacterial burden by determining ex vivo CFU isolated from skin punch biopsy specimens of the entire skin lesions obtained on day 3. Ex vivo CFU from CC398 (IHW398-1 and IHW398-2) and CC9 LA-MRSA-infected mice were significantly greater compared with SF8300-infected mice (Fig. 3), suggesting increased bacterial proliferation and/or persistence of these particular LA-MRSA strains in vivo.

LA-S. aureus-infected mice and local cytokine, chemokine, and growth factor levels. At day 3, SF8300-infected mice had significantly greater protein levels of IL-1β compared with all LA-MRSA-infected mice ($p < 0.05$) (Fig. 4A). IHW398-1, IHW398-2, and NCHW9-infected mice had significantly greater protein levels of IL-6 compared with the CC8 strains SF8300 and NCHW8 ($p < 0.05$) (Fig. 4A). IHW398-1, IHW398-2, and NCHW9-infected mice also had significantly increased protein levels IL-12(p70) compared with SF8300-infected mice ($p < 0.05$) (Fig. 4A). Proteins that showed no difference between LA- and CA- S. aureus infected mice were IL-10 (Fig. 4A), TNF, IL-12(p40), LIF, MIG, M-CSF, VEGF, and MPO and several cytokines were below the limit of detection (IFN-γ). CC8 strains SF8300 and NCHW8 had lower IL-1β and MIP-2 but higher levels of IL-6 and IL-12(p70) compared with SF8300.

Whole-genome sequencing analysis (WGSA) of CA- and LA-S. aureus. Figure 5 displays genomes hits for VFs and acquired AMR genes present in at least one of the 55 S. aureus genomes. WGSA of VF genes led to the following key findings (Fig. 5A). First, MSCRAMM genes clfA, clfB, fnbA, and fnbB, known to play a role host cell adhesion, are present among CA- and LA- S. aureus strains. Second, human IEC genes scn and sak were present among CC8 isolates and were absent from LA-MRSA CC398 and CC9 isolates. Third, the splA, splB, and splC genes encoding serine proteases, and reported to increase virulence in vivo, present only among the CC8 strains. The nor gene encoding for a nitric oxide reductase enzyme has also been reported to increase S. aureus virulence but was only present among the LA-S. aureus CC398 strains. Fourth, hemolysin genes hla, known to play a critical role in dermo-necrosis, and the hlgA, hlgB, and hlgC genes were conserved across CA-MRSA and LA-S. aureus isolates. hlb appeared to be truncated in the CA-MRSA strain and intact in the LA-S. aureus strains. Fifth, the leukotoxin encoding genes lukD and lukE, known to induce inflammation and dermonecrosis, were present among CC8 S. aureus isolates, but only the SF8300 CC8 isolate carried the Panton-Valentine Leukocidin encoding genes lukF-PV and lukS-PV. lukA and lukB genes encoding for the bicomponent LukAB leucocidin were present among CA- and LA- S. aureus genomes. Lastly, both CC398 LA-MRSA isolates did not contain any known enterotoxin genes typically encoded on prophages and pathogenicity islands.
The genes encoding enterotoxin K (sek) and enterotoxin Q (seq) were conserved across CC8 isolates, while the SSTI-associated NCHW8 CC8 isolate additionally carried the enterotoxin A (sea) and enterotoxin C (sec) encoding genes. Unique to the CC9 LA-MDRSA isolate was the egc cluster, encoding for enterotoxin G, I, M, N, and O (seg, sei, sem, sen, seo).

WGSA of AMR genes led to the following key findings (Fig. 5B). First, the mecA gene, encoding for methicillin resistance, was absent from LA-MDRSA, but these isolates carried the beta-lactamase encoding gene blaZ. Second, both CC398 and the CC9 LA-MDRSA genomes encoded for tetracycline resistance. The CC398 isolates carried a tet(M) gene, while the CC9 isolate carried a tet(L) gene. Third, macrolide resistance encoding genes were found only in LA-MDRSA isolates. The NCHW8 and NCHW9 isolate carried the erythromycin resistance encoding gene erm(A), and the IHW398-2 and NCHW9 isolates carried the ATP-binding protein encoding gene vga(A) conferring resistance to streptogramin A antibiotics. Fourth, unique to the IHW398-1 isolate, responsible for a recurrent SSTI in an IHO worker27, was the dfrG gene encoding resistance to trimethoprim antibiotics. Fifth, the spc gene, conferring resistance to spectinomycin, was found only in the LA-MDRSA isolates collected from IHO workers in North Carolina (NCHW8 and NCHW9). Finally, unique to the NCHW8 isolate was the aac(6′)-aph(2′) gene conferring resistance to gentamycin.

Discussion
The results of this study demonstrate an increased degree of pathogenicity associated with LA-S. aureus, marked by increased lesion size and bacterial burden, compared to CA-MRSA in a mouse model of SSTI. The IHW398-1 isolate in particular, which belongs to the LA-CC398-IIa lineage and produced a recurrent SSTI in an IHO worker27, displayed the greatest degree of pathogenicity and a MDRSA phenotype. It is notable that the lesion size of the NCHW9 LA-CC9 isolate was equivalent to the CA-MRSA strain (SF8300). Additionally, the S. aureus CFU counts recovered from the NCHW9 LA-CC9 infected lesions were significantly greater than the CA-MRSA strain (SF8300) and comparable to those of the highly pathogenic IHW398-1 LA-CC398-IIa strain, suggesting that the...
CC9 LA-MDRSA strain displays increased bacterial proliferation and/or persistence *in vivo*. This is important because the CC9 lineage of *S. aureus* is emerging as a predominant clone among IHO workers and community residents in North Carolina. As our efforts to understand and combat the environmental and community origins of antimicrobial-resistant *S. aureus* infections become a priority, it is critical that we continue to monitor the spread of LA-*S. aureus* into human populations and further elucidate mechanisms of virulence and pathogenicity of LA-*S. aureus* that have contributed to human morbidity.

We observed that the host cytokine and chemokine response to LA-*S. aureus* strains differed from that of CA-MRSA. Neutrophil derived IL-1β plays a critical role in amplifying and maintaining a neutrophilic response for abscess formation and bacterial clearance, and previous studies have reported that *S. aureus*-infected IL-1β-deficient mice develop larger skin lesions with higher bacterial counts than wildtype mice. An optimal response to *S. aureus* SSTI is associated with elevated local IL-1β protein levels, and engulfment of *S. aureus* by polymorphonuclear cells (PMNs) is known to alter macrophage production of IL-6, which subsequently lowers secretion of IL-1β. Our cytokine results indicated that the host response to LA-*S. aureus* infections might be suboptimal, as LA-*S. aureus*-infected mice had larger lesions, higher bacterial burden and decreased IL-1β and MIP2 and increased IL-6 levels compared with SF8300-infected mice. Neutrophil recruitment to the site of *S. aureus* infection in the skin is an event required for bacterial clearance, and, based on our cytokine data, may be attenuated among LA-*S. aureus* infected mice. A possible explanation for these findings is that LA-*S. aureus* have a distinct VF repertoire that might have suppressed the optimal IL-1β neutrophilic response required for bacterial clearance of *S. aureus* from the site of the SSTI. *S. aureus* alpha-toxin, for example, has been shown to suppress local IL-1β production in a mouse model of SSTI. Future studies should include abscess and skin pathology, which could help in characterizing the recruitment of immune cell populations to the site of infection.

**Figure 5.** Virulence factor and AMR genes in LA-*S. aureus* and CA-MRSA. The presence of a genome hit (indicated by red shading) was defined >85% gene identification similarity and >60% gene length similarity and confirmed by manual inspection. (A) Microbial surface components recognizing adhesive matrix molecules (MSCRAMM), human immune evasion, metabolic enzyme, hemolysin, leucocidin/toxin, and *Staphylococcal* enterotoxin gene genome hits generated via VirulenceFinder 1.5 or ABRicate tool. (B) Acquired antimicrobial resistance gene genome hits generated via ResFinder 3.0. Note. LA = livestock-associated. CA = community-associated. MRSA = methicillin-resistant *S. aureus*. MDRSA = multidrug-resistant *S. aureus*. 
Although all the isolates displayed phenotypic hemolysis, our WGSA revealed that only LA-\textit{S. aureus} CC398 and CC9 carried an intact beta-hemolysin gene. An insertion of the Sa3 prophage into the beta-hemolysin gene\textsuperscript{52} results in a truncated beta-hemolysin gene in both of the CC8 genomes (SF8300 and NCHW8). A previous study has reported that mutant strains lacking the Sa3 prophage, thereby carrying an intact beta-hemolysin gene, display a greater degree of hemolysis compared to its wild type\textsuperscript{59}. An intact \textit{hbl} gene has been previously shown to increase \textit{S. aureus} fitness for colonization and persistence in mice\textsuperscript{53}. However, a critical role for \textit{hbl} in the pathogenesis of SSTI is not entirely clear\textsuperscript{41}. The gain of an intact beta-hemolysin gene is dependent on the loss of human immune evasion cluster (IEC) genes – the Sa3 prophage can carry several human IEC genes including \textit{scn} and \textit{sak}\textsuperscript{52}, which were absent from the genomes of the LA-\textit{S. aureus} CC398 and CC9 isolates (IHW398-1, IHW398-2, and NCHW9). The staphylococcal complement inhibitor protein has been reported to be highly immunogenic\textsuperscript{54} and functional only against components of the human immune system\textsuperscript{52}. A loss of the Sa3 prophage and its associated proteins may provide improved virulence for LA-\textit{S. aureus} CC398 in a mouse model of SSTI. Similar to IEC encoded proteins, leukocidins largely lack activity in mice\textsuperscript{45} but are highly immunogenic\textsuperscript{50,56}. MGE encoded leukocidin genes\textsuperscript{57} \textit{lukE} and \textit{lukD}, encoding for \textit{LukED}, and \textit{lukS-PV} and \textit{lukF-PV}, encoding for PVL, were absent from the LA-\textit{S. aureus} CC398 and CC9 genomes. Thus, the loss of MGE encoded leukocidins may also provide improved virulence in a mouse model of SSTI. The \textit{nor} gene encoding for a nitric oxide reductase enzyme, commonly associated with pathogenic bacteria, and hypothesized to provide improved virulence and fitness for \textit{S. aureus} infections in vivo\textsuperscript{60}, was also only found among the LA-\textit{S. aureus} CC398 isolates that produced the largest lesions (IHW398-1 and IHW398-2). Taken together, multiple genetic differences between LA- and CA-\textit{S. aureus}, including the gain or loss of a combination genes encoding for important hemolytic toxins, leukocidins, and immune evasion proteins, could play a role in the observed pathogenicity of LA- and CA-\textit{S. aureus} SSTI in mice.

Our study had several strengths. First, this was to our knowledge, the first experimental design involving LA-\textit{S. aureus} strains isolated from nasal carriage and SSTI events of IHO workers in the United States. Second, this study was the first, to our knowledge, to characterize the relative pathogenicity of a LA-\textit{S. aureus} CC9 strain, which appears to be an emerging clone among IHO workers in North Carolina and Asht\textsuperscript{11,12}. Finally, we compared all LA-\textit{S. aureus} strains to a well-characterized USA300 CC8 strain that has consistently demonstrated substantial pathogenicity in C57BL/6 mouse models of SSTI and capacity to cause human infections in community settings\textsuperscript{29,30}.

Our study also has several limitations. First, certain \textit{S. aureus} virulence factors (VF) expected to increase pathogenicity may have low, or no activity in a mouse model of SSTI, such as PVL, HlgAB, and HlgBC\textsuperscript{45}. Furthermore, LA-\textit{S. aureus} largely do not carry human immune evasion cluster (IEC) genes, \textit{scn} and \textit{sak}\textsuperscript{52}, suggesting a host adaptation to animals\textsuperscript{11}. Thus, these results should be interpreted within the limitations of using a mouse model to compare the virulence of the included \textit{S. aureus} strains. Finally, our study characterizes the pathogenicity of a single LA-\textit{S. aureus} nasal carriage isolate, whereas isolates within the LA-\textit{S. aureus} CC398 and CC9 lineages display considerable diversity. Thanh-Thanh et al. report a conservation of core-genome elements, such as \textit{spa} type, between nasal carriage isolates within individual, but more heterogeneity between isolates for mobile genetic element (MGE) encoded genes, such as \textit{scn} and AMR genes\textsuperscript{45}. Differences in pathogenicity between closely related isolates of \textit{S. aureus} is well established, and future studies should compare multiple isolates of each lineage to improve confidence in lineage related pathogenicity conclusions.

Conclusions

The increased pathogenicity and bacterial burden associated with LA-\textit{S. aureus} skin infection compared to a highly virulent CA-MRSA skin infection raises both occupational and public health concerns of critical importance. Multiple epidemiologic studies have concluded that exposure to LA-\textit{S. aureus} is associated with SSTI among IHO workers and their household contacts\textsuperscript{4,5,9,10,27} and community residents with no known exposure to livestock\textsuperscript{18,19}. Thus, our pathogenicity findings suggest that infections with LA-\textit{S. aureus}, which are not limited to the occupational setting, could represent a broader public health concern. Particularly concerning is that these LA-\textit{S. aureus} strains are largely multidrug-resistant\textsuperscript{43,44}, which may have clinical implications regarding treatment of LA-\textit{S. aureus} infections. The results of this study provide new insights into the pathogenicity of emerging LA-\textit{S. aureus} strains that are commonly contracted by IHO workers and emerging among populations with no known livestock exposure. Mice infected with LA-\textit{S. aureus} displayed increased or equivalent pathogenicity in a mouse model of SSTI compared to USA300 clone, SF8300, marked by larger lesion sizes and higher bacterial burden. IL-1\beta signaling was significantly diminished among LA-\textit{S. aureus} infected mice compared to CA-MRSA infected mice, suggesting suboptimal immune cell recruitment for bacterial clearance during LA-\textit{S. aureus} infections. WGSA suggests that a subset of VF genes involved in the pathogenesis of \textit{S. aureus} SSTIs were present among CA-MRSA and LA-\textit{S. aureus} isolates, while LA-\textit{S. aureus} isolates carried a greater frequency and diversity of AMR genes encoding for resistance to antibiotics that are critically important for human health\textsuperscript{50}. Therefore, future research efforts should be considered to prevent exposure to LA-\textit{S. aureus} strains and study, monitor, and determine virulence mechanisms, host immune responses and response to treatment in humans that suffer SSTI caused by LA-\textit{S. aureus} strains.

Data Availability

The datasets generated during and/or analyzed during the current study are available from the corresponding author upon request.

Acknowledgements

The authors acknowledge Nicole Kwiatkowksi and Tracy Howard (Johns Hopkins Hospital Medical Microbiology Laboratory) for assistance with microbiology procedures and sample analysis. Funding for the study was provided by National Institute for Occupational Safety and Health (NIOSH) pilot award from the Johns Hopkins NIOSH Education and Research Center grant T42OH008428, NIOSH grant K01OH010193, Award 018HEA2013 from the Sherrilyn and Ken Fisher Center for Environmental Infectious Diseases Discovery Program at the Johns Hopkins University, School of Medicine, Department of Medicine, Division of Infectious Diseases. P.R.R. was supported by NIOSH grant T42OH008428, J.L., L.B.P and M.A. were supported by the NIAID-NIH grant R01AI101371. C.D.H. was supported by NIH grant R01ES026973, NIAID-NIH grant R01AI101371, and NSF grant 1316318 as part of the joint NSF-NIH-USDA Ecology and Evolution of Infectious Diseases program. L.S.M was supported by NIH grants R01AR069502, R01AR073665, and R21AI126896. T.C.S. was supported by R18 grant HS019966 from the Agency for Healthcare Research and Quality. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Author Contributions

P.R.R., C.D.H. and L.S.M. conceived the research question and designed the experiments. K.C.C. conducted antibody susceptibility testing on the isolates. C.D.H., T.C.S. and L.S.M. conceived the research question and designed the experiments. K.C.C. conducted the research. C.A.D. and L.S.M. provided S. aureus isolates. C.A.D. and L.S.M. conceived the research question and designed the experiments. K.C.C. conducted the research. L.S.M. provided support in the form of grants from the Sherrilyn and Ken Fisher Center for Environmental Infectious Diseases Discovery Program at the Johns Hopkins University, School of Medicine, Department of Medicine, Division of Infectious Diseases. P.R.R. performed the research. L.S.M. prepared the manuscript and figures, and all authors reviewed the manuscript.

Additional Information

Supplementary information accompanies this paper at https://doi.org/10.1038/s41598-019-42919-y.

Competing Interests: L.S.M. reports grant support from MedImmune, Regeneron Pharmaceuticals, Moderna Therapeutics, and Pfizer, which are developing therapeutics and vaccines against S. aureus and other pathogens.
