Abstract: Ab initio calculations using the local spin density approximation and also including the Hubbard $U$ have been performed for three low energy configurations of the interface between LaAlO$_3$ and TiO$_2$-anatase. Two types of interfaces have been considered: LaO/TiO$_2$ and AlO$_2$/TiO$_2$, the latter with Ti-termination and therefore a missing oxygen. A slab-geometry calculation was carried out and all the atoms were allowed to relax in the direction normal to the interface. In all the cases considered, the interfacial Ti atom acquires a local magnetic moment and its formal valence is less than +4. When there are oxygen vacancies, this valence decreases abruptly inside the anatase slab while in the LaO/TiO$_2$ interface the changes are more gradual.

Keywords: oxides, magnetism, ab-initio calculation

I. INTRODUCTION

Complex oxide heterostructures have been the subject of many recent papers, both experimental and theoretical, as their interesting interface properties promise to pave the way towards novel electronic devices. With the current available experimental techniques oxide thin films can be produced with a high degree of crystallinity and the electronic structure of their surfaces and interfaces can be precisely determined. The most studied system consists of two perovskite structures stacked along the (001) direction, in which they present alternate layers of LaO, AlO$_2$, TiO$_2$ and SrO with a very small lattice mismatch between them. A similar but less studied interface is that of LAO with TiO$_2$-anatase, that presents an even smaller lattice mismatch, namely less than 0.1%, along the (001) direction. TiO$_2$ is a key material for most applications, including catalytic and optical devices, sensors, optoelectronics and spintronics. Anatase thin films are frequently grown over LAO by pulsed laser deposition. It seems therefore important to perform a careful characterization, both from theory and experiments, of the film/substrate interface. Just to mention one example where this study may be relevant, room temperature ferromagnetism has been obtained from doped and undoped anatase films grown over LAO and the results strongly depend on the growth conditions.

There are two possible interfaces for the system LAO/TiO$_2$-anatase, namely LaO facing TiO$_2$ and AlO$_2$ facing TiO$_2$. Due to the ionicity of the component oxides, and in particular, to the fact that the layers of LAO (AlO$_2$ and LaO) have alternating formal charges (-1 and +1, respectively), there is an interfacial formal excess charge that should be compensated either by the presence of terraces with different stacking, or by oxygen vacancies or by atomic interdiffusion.

Experimental work has shown that, in the case of LAO/TiO$_2$-anatase, terraces with both types of interfaces appear and approximately in the same proportion. For the theoretical modeling of this system the fact that the TiO$_2$-anatase layers along the (001) direction are not strictly planar must be taken into account. As a consequence, the anatase interface can be either oxygen-terminated and thus neutral (with formal valence +4 for the interfacial Ti ion), or Ti-terminated. The latter situation is equivalent to considering surface oxygen vacancies and gives rise to a change in the valence of the interfacial Ti ion.

In this paper we study the electronic and magnetic properties of interfaces for different stackings of LAO/TiO$_2$ using density functional theory in the local density approximation (LSDA) and also considering electronic correlations in the framework of the LSDA+U approximation.

II. METHOD OF CALCULATION

To simulate the interfaces, we use a periodically repeated slab-geometry with 5 layers of each of the component materials and enough empty space between slabs so that they do not interact with each other (see Fig.1).

The cell parameters in the plane of the interface are kept fixed to those of the experimental bulk LAO (3.79 Å) and the positions of all atoms are allowed to relax in the out of plane direction until the forces are smaller than 0.05 eV/Å.

As in our previous work, we use an odd number of layers of LAO to avoid the formation of a large dipole moment, but we are aware that with this procedure it is difficult to assure whether the interface will be conducting or not. The reason lies in the fact that an LSDA calculation for a positively (negatively) charged system will locate the Fermi level in the conduction (valence) band.

We use the Wien2k code, that is an implementation of the full potential linear augmented plane waves method (FP-LAPW). The calculations are scalar relativistic and the parameters used are listed on Ref. It is well
known that in the case of oxides there is a band gap underestimation when using local exchange correlation functionals within density functional methods. For this reason, we have performed calculations with both the LSDA and the LSDA+U approximations\cite{ref23} using U=0.4 Ry for the Ti d orbitals\cite{ref24}, as in previous works. The comparison between the two procedures will evidence whether there is a qualitative difference in the interfacial properties due to electron correlations, as for example, a change in the valence of the Ti ions.

III. RESULTS

The total energies of different possible structures (at 0K and with collinear spins) have been evaluated in previous works\cite{ref4,ref5}, and in this paper we present the results for the lowest energy ones. For the interface in which LaO faces TiO$_2$ (Fig.1(a)), the oxygen-termination for anatase is preferred. However, when AlO$_2$ faces TiO$_2$, the lower energy is for the Ti-termination, thus with oxygen vacancies\cite{ref4,ref5}. Two types of Ti-terminated interfaces are studied: one where the interfacial Ti atom faces the hollow site of the Al atoms in the AlO$_2$ layer (Fig.1(b)) and another one where the Ti atom faces a bridge position of the Al sites in the AlO$_2$ plane (Fig.1(c)).

In all the cases considered there is a total formal charge of +1 arising in (a) from the LAO slab while in cases (b) and (c) it is due to the contribution of both the LAO slab and the oxygen vacancy in the anatase slab. We point out that there are more possible structures for each type of stacking, and that in this work we consider three of the lowest energy ones, those that require more energy to separate LAO from anatase. LaO/TiO$_2$ has the lowest energy, followed by AlO$_2$/TiO where oxygen vacancies are present\cite{ref4,ref5} (i.e. O2 is removed in Fig.1(b) and (c)). In the hollow structure one oxygen atom from the AlO$_2$ layer moves towards the interfacial Ti thus increasing its number of neighbors. This relaxation decreases the total energy of the system with respect to the bridge structure by 0.2 eV in LSDA and 0.4 eV in LSDA+U.

Fig.2 shows the densities of states (DOS) for the three structures depicted in Fig.1. We present the results for the LSDA+U approximation as they are similar to the LSDA ones and if there are any differences, they are mentioned in the text. On the left side of Fig.2 we present the total DOS and the partial contributions from the La atoms. On the right side, the DOS projected on the Ti atoms are shown in a zoomed-in region close to the Fermi energy ($E_f$). As in the case of pure anatase, the valence band is mostly from the oxygen atoms and the conduction band from the Ti atoms, with the $t_{2g}$ orbitals clearly separated by symmetry: the $t_{2g}$ levels closer to $E_f$ and the $e_g$ ones at higher energies. There are no Al states close to $E_f$, but oxygen atoms from LAO contribute significantly to the higher energy part of the valence band.

LaO/TiO$_2$ interface

In this interface (Fig.1(a)), $E_f$ is in the conduction band, as expected due to the formal charge in the LAO slab. The largest contribution to the occupied states close to $E_f$ comes from the interfacial Ti ion and the rest of the Ti atoms contribute less as the distance to the interface increases, as shown in Fig.2(top-right). This is true for both LSDA and LSDA+U approximations. It is interesting to note that similar layer projected DOS were obtained for LAO/STO even though in that structure, the TiO$_2$ planes alternate with SrO layers. The authors also find that the charge distribution is not affected by the inclusion of correlation. There is certainly no contribution from the interfacial La ions to the occupied states, as that peak is shifted towards the right when compared...
FIG. 2: Densities of states for the three slabs of Fig. 1 in the LSDA+U approximation. (a) Top: LaO/TiO$_2$, (b) Middle: AlO$_2$-hollow, (c) Bottom: AlO$_2$-bridge. The Fermi level ($E_F$) is marked by the dotted vertical line. Positive and negative values correspond to majority and minority spins, respectively. Left: total densities of states of the slabs and La levels. Right: Partial DOS on the Ti atoms zoomed-in around $E_F$. The labels of the Ti projected DOS are the same for the 3 cases. In the legend, the number by the atoms indicate the number of planes away from the interface.
FIG. 3: LSDA+U charge density of states close to $E_f$ in the plane defined by the Ti-Ti bonds for one unit cell. The occupied states in the energy range: $[E_f-1.5\text{eV}, E_f]$ are plotted for the three structures in Fig.1, namely (a) LaO/TiO$_2$, (b) AlO$_2$-hollow, (c) AlO$_2$-bridge. Charge isolines are spaced 0.01, from 0.01 to 1.00. In each case, the Ti interfacial atom is placed at the center of the figure, so as to make them comparable.

FIG. 4: Magnetic moment inside the Ti muffin-tin spheres as a function of the penetration in the anatase slab. The interface is at layer 0 and the surface is at layer 4.

with the La atom at the free surface of the slab (see Fig.2(a)). The charge density at the interface is plotted in Fig.2(a) and shows clearly the shape of the Ti $d$ orbitals. The main occupation comes from $d_{xz}$ and $d_{3z^2-r^2}$. A small total magnetic moment is obtained for the unit cell, distributed among all the Ti atoms (see Fig.3).

AlO$_2$/TiO-hollow interface

This interface (Fig.1(b)), presents a difference between LSDA and LSDA+U approximations. In LSDA+U, the majority spin of the interfacial Ti $d_{xy}$ orbital shifts towards lower energies, so that the system becomes a semiconductor with a small gap of 0.1 eV (see Fig.2(b)). This shift is smaller in the LSDA, so that the system is metallic. In Fig.3(b) we show the charge density at the anatase side of the interface where the $d_{xy}$ symmetry is evident. Both the charge and the magnetic moment at the Ti ions are large at the interface and decrease abruptly inside the anatase slab (see Fig.4).

AlO$_2$/TiO-bridge interface

In this interface (Fig.1(c)), $E_f$ lies in the conduction band, and the La peaks are further away from it, overlapping the $t_{2g}$ orbitals of the Ti atoms. The same result is obtained with LSDA. The interfacial Ti orbitals have different symmetry from those of the hollow case, being of $e_g$ character: $d_{x^2-y^2}$ and $d_{3z^2-r^2}$, as can be seen in Fig.2 and Fig.3. In this case, the $e_g$ levels split into two regions: one occupied band close to $E_f$ and another one at energies above the $t_{2g}$ orbitals, in the conduction band. The extra charge and the magnetic moment are both localized at the interface, near the oxygen vacancy, and their magnitude decreases abruptly inside the anatase slab as can be seen in Fig.4. In this case, the interfacial Ti formal valence and the magnetic moment are smaller than in the hollow structure.

It is interesting to note that in AlO$_2$/TiO interfaces, there is no contribution of the Ti atom at the free surface in the occupied region of the conduction band, showing that a slab with 5 layers is a good enough approximation to account for interface properties.

There has been some controversy concerning the appearance of interfacial ferromagnetism in the LAO/STO interface\cite{14}, which may also be the case here. For this reason we performed calculations with a double size unit cell (54 atoms), for the AlO$_2$/TiO interfaces which present localized magnetism at the interface. We studied the magnetic interaction between the interfacial Ti atoms within the LSDA+U method, setting them both in parallel and
antiparallel configurations. The two solutions exist but the antiparallel one is lower in energy, indicating that a long-range ferromagnetic interaction will not arise from the considered concentration and distribution of oxygen vacancies in AlO$_2$/TiO interfaces. We do not exclude the possibility of ferromagnetism in LaO/TiO$_2$, but it would be minor and due to fact that all the Ti atoms have local magnetic moments, many magnetic configurations should be considered for this study.

To explore the consequences of a lower vacancy concentration, and also of a formally neutral system, we considered the double size unit cell in the hollow configuration with only one interfacial oxygen vacancy. In this calculation none of the Ti ions resulted Ti$^{+3}$ and no magnetic moments appeared. Thus, a charge imbalance is needed to obtain Ti$^{+3}$ ions and is also a necessary (but not sufficient) condition for the appearance of magnetism.

IV. CONCLUSIONS

The principal conclusion of this work is that whatever the origin of the charge at the interfaces, its main effect is to change the valence of the Ti atoms, either if it is due to the layered-structure of LAO or to the presence of oxygen vacancies in anatase.

In AlO$_2$/TiO, there are interfacial oxygen vacancies and the interfacial Ti atom close to the vacancy position, acquires an extra charge. In LaO/TiO$_2$, there are no oxygen vacancies as they are not electrostatically favored and the extra charge is distributed among all Ti atoms, with decreasing value as the distance from the interface increases. Our results indicate that the LaO/TiO$_2$ interface spans through several anatase layers while the AlO$_2$/TiO one is more localized and presents large local magnetic moments.

In experimental samples, co-existence of the studied interfaces and possibly others as well, is expected. As a consequence, small patches with different magnetic order might appear, thus giving rise to sample-dependent results.
