Abstract
We study a quantum dot strongly coupled to a single high-finesse optical microcavity mode. We use a rotating wave approximation (RWA) method, commonly used in ion–laser interactions, together with the Lamb–Dicke approximation to obtain an analytic solution of this problem. The decay of Rabi oscillations because of the electron–phonon coupling is studied at arbitrary temperature and analytical expressions for the collapse and revival times are presented. Analyses without the RWA are presented as means of investigating the energy spectrum.

1. Introduction
Semiconductor quantum dots (QD) have emerged as promising candidates for studying quantum optical phenomena [1]. In particular, cavity quantum electrodynamics (CQED) effects can be investigated using a single QD embedded inside a photonic nanostructure [2]. One of the most fundamental systems in CQED is an atom interacting with a quantized field [3]. Such a system has been an invaluable tool to understand quantum phenomena [4] as well as for considerations on its applications to realize quantum information [5]. Similar systems (in the sense of their treatment, applications, etc) like trapped ions interacting with lasers [6] have been shown to be an alternative for developing techniques for quantum information processing [7] and the study of fundamental effects [8]. Recent developments in semiconductor nanotechnology have shown that excitons in QD constitute yet another two-level system for CQED considerations, and several successful experiments have been carried out [9], see also the review [10]. Contrary to the atom–field interaction where dissipative effects can be fairly overlooked provided the coupling strength between atom and field is sufficiently large compared to the dissipation rate due to cavity losses, the physics of a QD microcavity is enriched by the presence of electro–electron and electron–phonon interactions. Thus, decoherence due to phonons may imply fundamental limitations to quantum information processing on QD CQED [11]. Here, we would like to analyse the effects of electron–phonon interactions on electron–hole–photon Rabi oscillations in CQED.

As in [12, 13], we will not apply the Born–Markov approximation [14], but will use a different technique for solving this problem. In particular, we will make use of techniques commonly applied in ion–laser interactions. It relies on the rotating wave approximation (RWA), and within this and the Lamb–Dicke approximation the Hamiltonian becomes diagonal with respect to the phonon subsystem, which is shown in section 2. In the validity regime of the RWA, the decoherence effect on the inversion, due to the phonon bath, is analysed in section 3 and analytical expressions for the collapse and revival times are given. The zero-temperature situation has been investigated in [13], while here we study the effects due to zero as well as nonzero temperatures (causing the collapse of the revivals), and also how different phonon mode structures affect the decoherence. A different method to treat the nonzero temperature case was discussed in [15], where the collapse time is obtained numerically. The dynamics beyond the RWA, shortly studied here in section 4, become highly complex as can be seen from the energy spectrum. In what sense the phonon decoherence could be used as a possible resource for various applications is briefly mentioned in the concluding remarks.
2. The model

We assume a simple two-level model for the electronic degrees of freedom of the QD, consisting of its ground state \( |g\rangle \) and the lowest energy electron–hole (exciton) state \( |e\rangle \), with the Hamiltonian \[ \hat{H} = \omega_{eg} \hat{a}^\dagger \hat{a} + \omega_{eh} \hat{a}^\dagger \hat{a} + g (\hat{a}^\dagger \hat{a} + \hat{a} \hat{a}^\dagger) + \sum_k \lambda_k (\hat{b}_k^\dagger \hat{b}_k + \hat{b}_k \hat{b}_k^\dagger) + \sum_k \omega_k \hat{b}_k^\dagger \hat{b}_k, \]

(1)

Here, \( \hat{a} = |e\rangle \langle g| \), \( \hat{a}^\dagger \) and \( \hat{b}_k \) are the annihilation operators for the cavity mode and the \( k \)-th phonon mode, respectively. By transforming into a rotating frame, with frequency \( \omega \)

\[ \hat{H} = \Delta \hat{a}^\dagger \hat{a} + \Delta \hat{a} \hat{a}^\dagger + \sum_k \lambda_k (\hat{b}_k^\dagger \hat{b}_k + \hat{b}_k \hat{b}_k^\dagger) + \sum_k \omega_k \hat{b}_k^\dagger \hat{b}_k, \]

(2)

where \( \Delta = \omega_{eg} - \omega \) is the detuning. The transformation \[ \hat{T} = \prod_k \text{e}^{\frac{i}{\Delta} \frac{\lambda_k}{\omega} (\hat{b}_k^\dagger \hat{b}_k - \hat{b}_k \hat{b}_k^\dagger)}, \]

(3)

is used to obtain the Hamiltonian \( \hat{H}_T = \hat{T} \hat{H} \hat{T}^\dagger \)

\[ \hat{H}_T = (\Delta - \Delta_\eta) \hat{a}^\dagger \hat{a} \sum_k \omega_k \hat{b}_k^\dagger \hat{b}_k + g \left( \hat{a}^\dagger \hat{a} + \hat{a} \hat{a}^\dagger \right) \sum_k \lambda_k (\hat{b}_k^\dagger \hat{b}_k + \hat{b}_k \hat{b}_k^\dagger), \]

(4)

with \( \eta_k = \lambda_k / \omega_k \), \( \Delta_\eta = \sum_k \omega_k \eta_k^2 \) as the so-called polaron shift [16] and \( \hat{D}_k(\eta_k) = \exp (\eta_k \hat{b}_k^\dagger - \eta_k \hat{b}_k) \). For simplicity, we look at the case \( \Delta = \Delta_\eta \) to obtain

\[ \hat{H}_T = g \left( \hat{a}^\dagger \hat{a} \sum_k \hat{D}_k(\eta_k) + \hat{a} \hat{a}^\dagger \sum_k \hat{D}_k(\eta_k) \right) + \sum_k \omega_k \hat{b}_k^\dagger \hat{b}_k. \]

(5)

Now by transforming into an interaction picture one obtains

\[ \hat{H}_I = g \left( \hat{a}^\dagger \hat{a} \sum_k \hat{D}_k(\eta_k \text{e}^{-i\omega t}) + \hat{a} \hat{a}^\dagger \sum_k \hat{D}_k(\eta_k \text{e}^{-i\omega t}) \right) + \sum_k \omega_k \hat{b}_k^\dagger \hat{b}_k. \]

(6)

The idea is now to apply the RWA on the above Hamiltonian, equivalent to neglecting all rapidly oscillating terms. However, a closer look at \( \hat{H}_I \) indicates that such a procedure is not straightforward. Normally \( \omega_k = \omega_0 k \), \( k = 1, 2, 3, \ldots \) and expanding the above exponents gives several time-independent cross terms leading to a complicated expression. However, it is known that the RWA is highly related to the Lamb–Dicke approximation [17]. In the Lamb–Dicke approximation, it is assumed that the variations of the exponents are smaller compared to the characteristic length of the phonon harmonic oscillators, typically \( \eta_k \ll 1 \). One finds that in order to fulfill the RWA, one normally needs to be in the Lamb–Dicke regime [17]. This observation helps us considerably in approximating the above Hamiltonian, since now the cross time-dependent terms arising from different \( k \)'s vanish as we assume \( \eta_k \ll 1 \). In this case, we can perform the RWA separately on each individual exponent to find

\[ \hat{H}_{\text{rwa}} = \hat{g} \left( \hat{a}^\dagger \hat{a} \sum_k L_{\hat{b}_k} \left( \eta_k^2 \right) + \hat{a} \hat{a}^\dagger \sum_k L_{\hat{b}_k} \left( \eta_k^2 \right) \right), \]

(7)

where \( L_{\hat{b}_k} \) are the Laguerre polynomials of the order \( \hat{n}_k \) [18, 19] and \( \hat{g} = g \exp (\xi / 2) \equiv g \exp \left( - \sum_k \eta_k^2 / 2 \right) \) is a rescaled Rabi vacuum frequency. We emphasize that to be consistent with the RWA and Lamb–Dicke approximation, only terms up to \( \eta_k^2 \) should be considered when the Laguerre polynomials are expanded in the small parameter \( \eta^2 \). This will be done in the following section. The parameter \( \xi \) is sometimes referred to as the Huang–Rhy factor [20], and it is usually very small, \( \xi \ll 1 \) [21, 22], but it can become much larger, \( \xi \sim 1 \) [23], and then our analysis would break down. The above equation is readily solvable, finding the evolution operator as

\[ \hat{U} = \hat{U}_{\omega \varepsilon} \hat{a}^\dagger \hat{a} \hat{a}^\dagger + \hat{U}_{\omega \varepsilon} \hat{a}^\dagger \hat{a} = + \hat{U}_{\omega \varepsilon} \hat{a} \hat{a}^\dagger - \hat{U}_{\omega \varepsilon} \hat{a} \hat{a}^\dagger, \]

(8)

where

\[ \hat{U}_{\omega \varepsilon}(t; \hat{n}_k) = \text{cos} \theta_k \hat{a}^\dagger \hat{a}^\dagger + \text{sin} \theta_k \hat{a} \hat{a}^\dagger, \]

(9)

\[ \hat{U}_{\omega \varepsilon}(t; \hat{n}_k) = -i e^{i \frac{\xi}{2}} \frac{\sin \theta_k \hat{a}^\dagger \hat{a}^\dagger}{\theta_k}, \]

(10)

\[ \hat{U}_{\omega \varepsilon}(t; \hat{n}_k) = -i e^{i \frac{\xi}{2}} \frac{\sin \theta_k \hat{a} \hat{a}^\dagger}{\theta_k}, \]

(11)

and

\[ \hat{U}_{\omega \varepsilon}(t; \hat{n}_k) = \text{cos} \theta_k \hat{a}^\dagger \hat{a}^\dagger, \]

(12)

with \( \hat{\theta}_k = e^{i \theta_k} \hat{n}_k \).

3. Dynamics

Having the evolution operator, we can in principle calculate any properties we want, in particular, we look at the Rabi oscillations for the two-level system. This quantity has as well been studied experimentally in QD systems [22]. By means of the inversion operator \( \sigma_z = |e\rangle \langle e| - |g\rangle \langle g| \)

\[ W(t) = Tr \{ \rho(t) \sigma_z \}, \]

(14)

where \( \rho(t) = \hat{U} \rho(0) \hat{U}^\dagger \) and \( \rho(0) \) is the initial density matrix, Rabi oscillations will be analysed. This initial state is chosen as the fully separable state

\[ \rho(0) = \prod_k \rho_k(0) |0, e\rangle \langle 0, e|, \]

(15)

with the QD excited, the cavity mode in vacuum and the phonon modes are all assumed to be in a thermal distribution

\[ \rho_k(0) = \sum_{n_k=0}^{\infty} |c_{n_k}|^2 |n_k\rangle \langle n_k| = \sum_{n_k=0}^{\infty} \frac{\eta_k^{n_k}}{\eta_k^{n_k} + 1} |n_k\rangle \langle n_k|. \]

(16)

The inversion can be written explicitly as

\[ W(t) = \sum_k \langle c_{n_k} \rangle \cos \left( 2 \hat{g} \sum_k L_{\hat{b}_k} \left( \eta_k^2 \right) t \right), \]

(17)
where the summation goes from 0 to ∞ and runs over all modes. For \( t = 0 \), we have \( W(0) = 1 \) as expected, while for \( t \neq 0 \) the sum will in general differ from 1. Interestingly, we note that at zero temperature, \( T = 0 \), \( |c_{n,k}| = \delta_{n,0} \) for all \( k \) and thus, at absolute zero temperature the system Rabi oscillations are intact but with a rescaled frequency \([13]\). The expression for the inversion can be simplified by taking into account that \( \eta \ll 1 \) and we therefore expand the Laguerre polynomials

\[
L_n(\eta^2) = \sum_{m=0}^{n} \binom{n}{m} \eta^{2m} = 1 - n\eta^2 + \frac{n(n-1)}{4} \eta^4 + \ldots .
\]  

(18)

Keeping only zeroth and first-order terms in \( \eta^2 \) in the assumed Lamb–Dicke regime, the inversion can be written, after some algebra, as

\[
W(t) = \cos(2\tilde{g}t)Re \left( \prod_{k} \frac{1}{\tilde{n}_k + 1 - \tilde{n}_k e^{-i2\tilde{g}t\eta_k^2}} \right)
- \sin(2\tilde{g}t)Im \left( \prod_{k} \frac{1}{\tilde{n}_k + 1 - \tilde{n}_k e^{-i2\tilde{g}t\eta_k^2}} \right).
\]  

(19)

In the following, we use dimensionless variables such that the QD-cavity coupling \( g = 1 \), but keep it in the formulas for clarity. There are some special cases worth studying separately.

3.1. Single-phonon mode

In the simplest case consisting of a single-phonon mode characterized by \( \eta \) and \( \bar{n} \), the inversion \((19)\) simplifies to

\[
W(t) = \frac{(\bar{n} + 1) \cos(2\tilde{g}t) - \bar{n} \cos[2\tilde{g}(1 - \eta^2)]}{(\bar{n} + 1)^2 + \bar{n}^2 - 2\bar{n}(\bar{n} + 1) \cos(2\tilde{g}t\eta^2)}.
\]  

(20)

The second term oscillates with a slightly shifted frequency compared to the first term causing a collapse of the inversion. When the two competing terms return in phase, at times

\[
t_{\text{rec}}^{(1)} = k \frac{\pi}{\tilde{g}\eta^2}, \quad k = 1, 2, 3, \ldots,
\]  

(21)

inversion revivals occur. These are perfect within the small \( \eta^2 \) expansion. For short times \( t \), the inversion may be further approximated to give

\[
W(t) = \frac{\cos(2\tilde{g}t)}{1 + 8\bar{n}(\bar{n} + 1)\tilde{g}^2t^2\eta^2}, \quad 2\tilde{g}t\eta^2 \ll 1
\]  

(22)

and we conclude that the envelope function, determining the collapse time, is a Lorentzian with width

\[
t_{\text{col}}^{(1)} = \frac{1}{\sqrt{8\bar{n}(\bar{n} + 1)\tilde{g}^2\eta^2}}.
\]  

(23)

In figure 1, we display two different examples of the atomic inversion \((17)\). The upper plot (a) has a large average number of phonons; \( \bar{n} = 40 \) and \( \eta = 0.01 \). In the lower plot (b), the number of phonons is instead \( \bar{n} = 2 \) and again \( \eta = 0.01 \). We can conclude that our results confirm that a lower temperature of the reservoir clearly increases the collapse time.

### Figure 1.

The atomic inversion \( W(t) \) as a function of time \( t \) for the single-mode bath. The dimensionless parameters are \( \eta = 0.01 \) and \( \bar{n} = 40 \) (a), and \( \eta = 0.01 \) and \( \bar{n} = 2 \) (b).

3.2. \( N \) identical phonon modes

By studying several identical phonon modes, one may see the effect of multi modes in a simple analytic way. Instead of approaching equation \((17)\), we go back to equation \((5)\) and let \( \eta = \eta_0 \) and \( \omega = \omega_k \) for all \( k \). Let us introduce an \( N \times N \) dimensional unitary operator connecting the boson operators \( \hat{b}_1, \hat{b}_2, \ldots, \hat{b}_N \) with new ones \( \hat{c}_1, \hat{c}_2, \ldots, \hat{c}_N \) such that

\[
\hat{c}_1 = \frac{1}{\sqrt{N}} \sum_{k=1}^{N} \hat{b}_k.
\]  

(24)

The unitary transformed Hamiltonian becomes

\[
\hat{H}_T = \hat{g} \left[ \hat{a}^\dagger \hat{\sigma} \hat{D}_{\hat{c}_i} \left( \eta \sqrt{N} \right) + \hat{\sigma} \hat{a}^\dagger \hat{D}_{\hat{c}_i}^\dagger \left( \eta \sqrt{N} \right) \right] + \omega \sum_{i} \hat{c}_i^\dagger \hat{c}_i.
\]  

(25)

Thus, the problem relaxes to the single-mode case with the scaled Lamb–Dicke parameter \( \eta \to \eta \sqrt{N} \).

3.3. \( N \) different phonon modes

In a more realistic model, the phonon bath consists of non-identical modes, and depending on the model studied, one has different spectral functions \( J(\omega) = \sum_k \lambda_k^2 \delta(\omega - \omega_k) \) \([25]\). For the frequencies of interest here, \( J(\omega) \) has a simple power law behaviour \([26]\), resulting in a

\[
\eta_k^2 = \kappa \omega_k^s, \quad s = \ldots, -2, -1, 0, 1, 2, \ldots
\]  

(26)

where \( \kappa \) is a constant. The power \( s \) depends on matter properties, for example, ohmic damping \( J(\omega) \propto \omega \), phonon damping \( J(\omega) \propto \omega^2 \) or impurity damping \( J(\omega) \propto \omega^3 \), but it also depends on system dimensions. We take \( \omega_k = \omega_0 k \), \( k = 1, 2, 3, \ldots \) such that \( \omega_0 \) determines the frequency spacing, while the thermal phonon distributions are determined from the average phonon numbers

\[
\bar{n}_k = \left[ \exp \left( \frac{\omega_k}{T} \right) - 1 \right]^{-1},
\]  

(27)
for some scaled temperature $\tilde{T}$. Often a frequency 'cut-off' is introduced for the spectral function, but because the vacuum modes do not affect the system dynamics in our case, such a cut-off is not needed. Defining $\gamma_k = \delta\eta_k(\tilde{n}_k + 1)\tilde{g}^2\eta_k^{2/3}$, and using the same arguments as above, the collapse time in the small $\eta$ expansion is given by

$$\prod_k (1 + \gamma_k t_{\text{col}}) = 2.$$  

By further introducing

$${r}_k = \sqrt{(\tilde{n}_k + 1)^2 + \tilde{n}_k^2 - 2\tilde{n}_k(\tilde{n}_k + 1)\cos(2\tilde{g}\eta_k t_r^2)},$$

$${\theta}_k = \arctan\left[\frac{\tilde{n}_k \sin(2\tilde{g}\eta_k t_r^2)}{\tilde{n}_k + 1 - \tilde{n}_k \cos(2\tilde{g}\eta_k t_r^2)}\right].$$

The approximated atomic inversion (19) can be written as

$$W(t) = \frac{\cos(2\tilde{g}\eta^2 t + \theta)}{r},$$

where $\theta = \sum_k \theta_k$ and $r = \prod_k r_k$. In figure 2, five examples of the atomic inversion are displayed for different powers $s$. Perfect revivals clearly occur for the $s=0$, $s=1$ and $s=2$ cases, while for $s=-2$ and $s=-1$ the revivals are never fully perfect even at long times. This is because if $s=0, 1, 2, \ldots$, we have $\eta_k = \kappa \omega_k^2 = \kappa a_k^2 k^4 = \tilde{n}_k^2 j$, where $j$ is a positive integer, which does not hold if $s=\ldots,-2,-1$. Note that the revivals are a consequence of the non-Markovian treatment of the problem; the dynamics is unitary and each phonon mode is considered at the same footing as the cavity mode and the QD themselves. Therefore, also when a large number of different phonon modes are coupled to the QD-cavity, the system exhibits revivals, although, less pronounced.

4. Beyond the RWA

So far, all the results have been derived within the RWA and the Lamb–Dicke approximation, which for $g\eta/\omega \ll 1$ is expected to be justified. In this section, we calculate the atomic inversion by numerically diagonalizing the truncated Hamiltonian of equation (5). The size of the Hamiltonian is chosen such that convergence of its eigenstates is guaranteed. We restrict the analysis to the one-phonon mode case, which already explains most effects. In the Fock state basis $|m\rangle$ of the phonon mode, the matrix elements of the Hamiltonian are obtained by using the formula

$$D_{mn} = \langle m|\hat{D}(\eta)|n\rangle = e^{-|\eta|^2/2} \frac{n!}{|n-m|!} \sum_{\delta=0}^{n-m} \frac{(-1)^\delta}{\delta!} \binom{n}{m} |\eta|^{2\delta} L_{n-m}^\delta(\eta^2),$$

where $L_j^m$ is an associated Laguerre polynomial.

For lowest order truncation of the Hamiltonian, one keeps only a single Fock state of the phonon mode, and the RWA results given above are achieved [27]. In this approximation, when the initial states of the phonon modes are of the form $|e_{n_j}\rangle = \delta_{n_j,0}$, the combined QD-cavity system persists perfect Rabi oscillations with a rescaled vacuum Rabi frequency $g \rightarrow \tilde{g}$ and the above approximation simply gives a rescaled frequency $g \rightarrow \tilde{g}$, which is the result presented in [13]. Thus, this simple derivation regains the results of [13], and it is also clear how the approximation comes about and may be easily extended to nonzero temperature phonon baths. A deeper insight of the approximation (RWA) is gained by increasing the size of the truncated Hamiltonian. In other words, to go beyond the RWA one needs to include more coupling terms arising due to the phonon bath. Considering an initial vacuum phonon mode and including first-order corrections to the RWA, the Hamiltonian can be written in matrix form (after an overall shift in energy) as

$$H_{\text{vac}} = \begin{bmatrix} -\frac{\omega}{2} & 0 & D_{00} & D_{01} \\ 0 & \frac{\omega}{2} & D_{01} & D_{11} \\ D_{00} & D_{01} & -\frac{\omega}{2} & 0 \\ D_{01} & D_{11} & 0 & \frac{\omega}{2} \end{bmatrix},$$

with eigenvalues

$$\lambda_{\pm} = -\frac{D_{00} + D_{11}}{2} \pm \frac{1}{2} \sqrt{(D_{00} - D_{11} + \omega)^2 + 4D_{00}^2},$$

$$\mu_{\pm} = \frac{D_{00} + D_{11}}{2} \pm \frac{1}{2} \sqrt{(D_{00} - D_{11} - \omega)^2 + 4D_{00}^2}.$$

These eigenvalues are shown in figure 3 as a function of $\omega$ for fixed $\eta$; $\lambda_{\pm}$ (solid lines) and $\mu_{\pm}$ (dashed lines). The bare curves, $\epsilon_{\pm}^b = -D_{ij} \pm \omega/2$ and $\epsilon_{\pm}^n = D_{ij} \pm \omega/2$, where $i=0, 1$, are coupled by the non-RWA term $D_{01}$. This causes the crossings at $\omega = 0$ to be avoided, and the degeneracies
are lifted. Thus, in the RWA, the difference in the values \( D_n \) for \( i = 0, 1, 2, \ldots \) of the bare energies at \( \omega = 0 \) causes the collapse–revival structure. However, the non-RWA terms start to dominate the spectrum, the bare energies are no longer proportional to \( \pm \omega \) and the full system dynamics will no longer show the nice collapse-revival structure. For which \( \omega \) that this non linear behaviour occurs, depends on \( g \) and \( \eta \).

A rough estimate can be derived by assuming that the linear dependence of \( \omega/2 \) should overrule the avoided crossing energy difference \( 2D_{01} \), which after expanding in \( \eta \) gives \( \omega \gg 4g\eta \). In other words, using our typical parameter values of the previous section, we note that when \( \omega < 1 \) the RWA is likely to break down. For small \( \omega \), the eigen energies are very densely spaced, and a small non-RWA correction will couple the different energies in an involved way. The number of states taken into account to correctly describe the dynamics is then growing rapidly, which can be seen in figure 4 showing the numerically obtained eigenvalues for a \( 12 \times 12 \) dimensional (a) and a \( 22 \times 22 \) dimensional (b) Hamiltonian. Clearly, the more the states are taken into account, the more complicated the energy spectrum.

Finally, in figure 5, we give one example of the numerically obtained inversion in a regime where the RWA is not justified. Interestingly, for \( \omega \ll 1 \) the state \( |g \rangle \) (opposite of the initial state) of the QD is more strongly populated, while for increasing \( \omega \) the collapse–revival pattern appears and \( W(t) \rightarrow 1/2 \) in the collapse regions.

5. Conclusions

We have studied a QD strongly coupled to a single high-finesse optical cavity mode by applying methods usually applied in ion–laser interactions, namely, the decomposition of the Glauber displacement operator in Laguerre polynomials. This allowed us to obtain results for the system when it is coupled to a phonon reservoir beyond the Born–Markov approximation. We have studied several cases, including \( N \) identical and \( N \) different phonon modes, i.e. the case of nonzero temperature. Expressions for the collapse and revival times of the Rabi oscillations have been derived analytically, valid in a large range of parameters.

The analysis is carried out in the resonance condition \( \Delta = \Delta_0 \), which in the RWA shows that no population is transferred between the QD and the phonon reservoir. If this resonance is not fulfilled, but other specific types of conditions are (blue or red detuned), one may derive different types of effective Hamiltonians in the RWA, in resemblance with ion-trap cavity systems [28]. Then, the effective models will be described by typical generalized two-mode Jaynes–Cummings Hamiltonians, which can often be solved analytically [28]. Another assumption made in the derivation is that the cavity mode is initially in vacuum, while for a general initial state each photon state will, just like in the case of the various phonon states, induce different Rabi frequencies affecting the collapse–revival pattern. Such a situation may be of interest for state preparation or state measurement and is left for future considerations.

We have also presented a short analysis of the dynamics in the non-RWA regime. In this parameter range, the energy spectrum becomes very complex with crossing energy curves, and as the energy spacing between the curves is small for these parameters, many eigenstates of the Hamiltonian must
be included in order to correctly describe the dynamics. Nonetheless, from such an approach it is seen how the RWA results are obtained as a first order correction to the trivial situation, and how higher order terms cause avoided crossings between the energies, and they are therefore no longer proportional to \( \pm \omega \) around the crossings which will induce a ‘breakdown’ of the collapse–revival pattern. The higher order terms in such an expansion can be seen as a virtual exchange of phonons [29].
