Abstract
Numerous studies have shown that statin therapy initiated early after heart transplantation improves the short- and long-term prognosis, leading to a reduction in the incidence of cardiac allograft vasculopathy (CAV), acute rejection episodes and significantly lowers the incidence of cancer in this patient population. The molecular mechanisms responsible for the beneficial effects of statins in patients after heart transplantation are complex; the effectiveness of statins is associated not only with their hypolipemic action, but also with their pleiotropic properties. Statins have been shown to exert protective and therapeutic effects against cancer because they act as antiproliferative agents, promoting apoptosis and inhibiting angiogenesis. Moreover, they reduce the number of circulating monocytes, which inhibits the secretion of proinflammatory cytokines, growth factors, adhesion molecules, chemokines, and matrix metalloproteinases, preventing chronic rejection and CAV. For these reasons, statins should be used as part of standard therapy in patients after heart transplantation.

Key words: statins, heart transplantation.

Introduction
Heart transplantation is a recognized and effective form of treatment for patients with end-stage cardiac insufficiency. Within the last several years, significant improvements have been made in transplantology – anesthesiological and surgical techniques have been perfected, state-of-the-art technology has been employed to store the organs, new immunosuppressive and antiviral agents have been developed, and changes have been introduced to the methodology of monitoring the concentrations of immunosuppressants. All these factors have facilitated the gradual prolongation of post-transplant survival.

Episodes of acute rejection and viral infections are considered to be among the significant causes of heart transplant failures in short-term follow-up. In turn, the long-term complications include chronic transplant rejection, malignant tumors, dyslipidemia, cardiac allograft vasculopathy (CAV), and renal failure [1-3]. The immunosuppressive therapy employed after heart transplantation is indispensable for preventing episodes of acute and chronic rejection; notwithstanding, it is associated with the occurrence of numerous adverse effects [2, 3]. There are many factors which impact the long-term survival of heart transplant patients; among them, the co-occurrence of additional cardiovascu-
lar risk factors and the proper selection of pharmacotherapy are considered particularly important [4, 5].

Numerous studies have demonstrated that statin treatment introduced early after heart transplantation improves both short- and long-term prognosis, reduces the prevalence of CAV and transplant rejection, and significantly lowers the prevalence of tumors in this patient population (Table I). Molecular mechanisms responsible for the beneficial effect of statins in heart transplant recipients have not yet been fully understood; however, it is known that the effectiveness of statins is associated not only with their hypolipemic action, but also with their pleiotropic properties. In this regard, it is especially noteworthy that their action is antineoplastic and immunomodulatory; it regulates endothelial activity and inhibits the development of CAV [5-8].

**Hypolipidemic properties of statins**

Dyslipidemia occurs in 60-80% of heart transplant recipients and is associated with the development of CAV. It is believed that its occurrence may be caused by genetic predispositions, infections, comorbid conditions such as diabetes or chronic kidney disease, obesity, heart failure of ischemic etiology, preoperative dyslipidemia, and the use of steroids and immunosuppressants [3, 9, 10].

Statins, whose mechanism of action is based on the competitive inhibition of HMG-CoA (3-hydroxy-3-methylglutaryl-CoA) reductase, play a significant role in the prevention and inhibition of post-transplant dyslipidemia progression [11]. A prospective randomized study conducted by Zakliczyński et al. demonstrated that 66% of heart transplant recipients have abnormal lipid profiles; this primarily pertains to elderly patients as well as patients with heart failure of ischemic etiology, obesity, arterial hypertension, and diabetes [4]. Magnani et al. analyzed the efficacy and safety of statin use in heart transplant recipients [12]. The patients included in their study were randomized into groups receiving atorvastatin or pravastatin. The study demonstrated a significantly more pronounced reduction of total cholesterol concentration, LDL fraction, and triglycerides in patients treated with atorvastatin as compared with the group receiving pravastatin [12]. In turn, the research conducted by Samman et al. indicates the effectiveness of rosuvastatin use in heart transplant recipients in whom previous therapy with other statins did not result in desired effects with regard to regulating their lipid economy [11]. One of the theories explaining the differences in statin action points to their different chemical structure, which determines their hydrophilic or lipophilic nature [13]. Heart transplant recipients often face the development of drug-resistant dyslipidemia; thus, the hypolipemic action of statins may be insufficient. In such cases, therapy employing ezetimibe combined with small doses of HMG-CoA reductase inhibitors may prove effective [14]. An observational study conducted by Quart et al. corroborates the efficacy and safety of combined treatment using simvastatin

TG – triglycerides, TC – total cholesterol, LDL – low density lipoproteins, CAV – cardiac allograft vasculopathy
and ezetimibe, the mechanism of which is based on inhibiting the absorption of cholesterol in the intestines [15]. Due to the different, but complementary mechanisms of these agents' action, combined therapy enables the achievement of better results than monotherapy, especially in patients in whom statin use does not enable the achievement of target lipid values [9]. Considering dose-dependent adverse effects of statins and the prevalence of dyslipidemia refractory to treatment among heart transplant recipients, introducing ezetimibe in monotherapy or in combination with statin should improve prognosis in this group of patients [14-16].

**Antineoplastic properties**

Neoplasms constitute one of the leading causes of mortality in the long-term follow-up of heart transplant recipients. Their etiology has four potential causes: genetic, environmental, and immunological factors, as well as viral infections. These factors may cause the activation of carcinogenic mechanisms, including damage of strategic DNA fragments, so-called proto-oncogenes, or tumor suppressor genes, changes in the regulation of cell growth, resistance to apoptosis, and sustained angiogenesis. The most important factors influencing the development of tumors in heart transplant recipients are the accumulated effect of immunosuppression (length of use and treatment intensity) and the coexistence of chronic viral infection. Immunosuppressive agents can damage deoxyribonucleic acid, causing neoplastic cell transformation and impairing normal immune mechanisms, which leads to uncontrolled growth and division of tumor cells. In turn, viruses cause neoplastic transformation of cells when they acquire cellular proto-oncogenes into their genome, integrate their genome with that of the host in the vicinity of proto-oncogenes, or encode viral oncogenes [2].

Much evidence has been gathered for the protective and therapeutic action of statins with regard to various neoplasms. This effect is dependent both on their hypolipemic and pleiotropic action. Statins inhibit cholesterol synthesis, primarily in hepatocytes, but also through the mevalonate pathway. By reducing the concentration of cholesterol in circulation, they reduce cholesterol concentration in many types of cells, including neoplastic cells, influencing the microdomains of cellular membranes and steriodogenesis. Furthermore, they inhibit the activity of cholesterol-dependent pathways in neoplastic tumors by influencing their microenvironment. The cholesterol-dependent effects of statin action have been confirmed by epidemiological studies, which demonstrated a positive correlation between hypercholesterolemia and the risk of aggressive prostate tumor development [17, 18]. In turn, in vitro studies have demonstrated the antiproliferative, proapoptotic, and antiangiogenic action of statins [19-21]. It has been determined that statins reduce the expression of the antiapoptotic Bcl2 protein and increase the expression of the proapoptotic Bax protein [22], thus intensifying the apoptotic effects of chemotherapeutic agents. Another protective effect of statins consists in the inhibition of the mevalonate pathway, which, in addition to its participation in cholesterol synthesis, plays a key role in the formation of isoprenoid precursors, necessary for the synthesis of Ras oncogenes. Ras oncogenes encode G proteins, which are responsible for the transmission of cellular information as well as for cellular proliferation, differentiation, and transformation. The inhibitory effect of statins on the mevalonate pathway reduces the concentrations of farnesyl diphosphate, geranylgeranyl diphosphate (GGDP), and dolichol, which are engaged in the post-translational modification of various proteins [23-25]. By inhibiting GGDP production, statins may reduce cell migration and exert an antiproliferative effect. In vitro studies on cerivastatin have demonstrated a dose-dependent reduction of the nuclear factor κ-light-chain-enhancer of activated B cells (NF-κB) and RhoA, resulting in smaller concentrations of matrix metalloproteinase and urokinase, which play a key role in cell migration [26] and reduce the metastatic potential of neoplastic cells. Fröhlich et al. demonstrated that the administration of statins after heart transplantation lowered the risk of tumor development and reduced overall mortality in this group of patients. Significantly, the obtained results were not dependent on the initial level of cholesterol, which indicates statin action that is different from and independent of its hypolipemic effects [5]. What is relevant is statin’s influence on the activity of matrix metalloproteinases and the level of cell adhesion molecules such as ICAM-1 and VCAM-1 [27]. The use of HMG-CoA reductase inhibitors results in a lower expression of cell adhesion molecules, which makes it more difficult for neoplastic cells to adhere to blood vessel walls, thus blocking the possibility of metastasis to other organs [8]. It has also been observed that statins inhibit blood vessel proliferation within the tumor, thus reducing the supply of substances required for neoplastic cell growth and, thereby, limiting further tumor growth [28]. Numerous studies demonstrate that the use of statins in heart transplant recipients reduces the risk of large intestine, ovarian, pancreatic, and breast tumors, as well as skin tumors, which are otherwise commonly observed in heart transplant recipients [2, 28]. As a result, the prevalence of all-cause mortality in this patient population is lower [29].

**Immunomodulatory properties**

Statins influence many components of the immune system. One of the possible immunomodulatory mechanisms of this group of agents is the reduction in the expression of major histocompatibility complex (MHC) class II, which is constitutively present on macrophages, B lymphocytes, and dendritic cells, resulting in a weakened capacity for antigen presentation to T lymphocytes [7]. HMG-CoA reductase inhibitors may also inhibit the expression of MHC II on the surface of endothelial cells stimulated by IFN-γ [30]. The observed reduced activity of this system contributes to the lowering of graft rejection prevalence in patients treated with statins [7, 30]. It has also been demonstrated that
administering statins to heart transplant recipients lowers the circulatory concentration of monocytes, which are engaged in the mechanisms of graft rejection. Lowering the expression of these multi-functional cells of the immune system is associated with inhibiting the secretion of many substances, such as proinflammatory cytokines, growth and adhesion factors, chemokines, and matrix metalloproteinases, contributing to the inhibition of the chronic rejection process [31]. The results of studies conducted to date suggest that statins have a regulatory impact on the mechanisms of humoral and cellular response [1, 7, 32]. It appears that these agents can also be employed as immunomodulators in all those conditions which stem from the abnormal expression of MHC class II molecules [7].

**Inhibiting the development of cardiac allograft vasculopathy**

Despite advances in immunosuppressive treatment, CAV is one of the leading causes of death in heart transplant recipients who have survived the first year after the transplant, along with graft insufficiency and cancer [33]. CAV pathogenesis has not yet been fully elucidated; nonetheless, CAV is considered to be a multifactorial condition, in which the key role is played by the mechanisms of congenital and acquired immune response as well as by non-immune mechanisms, which may modify the response of the immune system to the transplanted organ. Endothelial dysfunction, hyperlipidemia, as well as the increased expression of adhesion molecules, proinflammatory cytokines, and the recently discovered toll-like receptors contribute to the development of diffuse vasculopathic changes in the transplanted organ, which may lead to graft dysfunction [32, 34]. A high concentration of total cholesterol concomitant with a low HDL concentration or the isolated occurrence of one of the listed factors increase the risk of CAV development in the population of heart transplant recipients [4]. An important role in the described process is also played by other factors, including HLA mismatch between the donor and the recipient, immunosuppressive agents, and cytomegalovirus infection [1]. It is also important to note the significant difference between atherosclerosis developing for years in native coronary vessels, which pertains to all layers of proximal epicardial artery segments, and changes within the coronary vessels of a transplanted heart, which develop very rapidly, in a diffuse and concentric manner, and without calcifications, involving the internal layer of both arteries and veins in their medial and distal segments [35]. Thus, the options of interventional treatment are limited in the case of cardiac allograft vasculopathy. The management strategy for heart transplant recipients should, therefore, aim to prevent and treat the factors which favor CAV occurrence.

Prophylaxis based on inhibiting the excessive activity of endothelial vessels is of particular importance. It has been established that simvastatin and pravastatin inhibit CAV development by reducing cholesterol concentrations, exerting a favorable influence on the endothelium (independent of their hypolipidemic action) and exhibiting direct anti-inflammatory activity [1, 36-38]. The results of an analysis performed by Mahle et al. confirm the favorable role of statins in children after heart transplantation. The authors of the mentioned study demonstrated that the use of pravastatin was associated with a significant reduction in cholesterolar concentration and CAV prevalence [6]. A study conducted by Grigioni et al. also confirmed the efficacy of statins in preventing the development of cardiac allograft vasculopathy in transplanted hearts [39]. It should be underscored that the impairments in myocardial perfusion caused by CAV contribute significantly to graft failure [25]. Based on retrospective observations, Stojanovic et al. reached the conclusion that the use of pravastatin in heart transplant recipients improves survival, lowers the risk of CAV, and reduces the prevalence of hemodynamically significant episodes of graft rejection in 5-year follow-up [1]. Wenke et al. demonstrated significantly better prognosis in heart transplant recipients treated with statins over the period of 11 years of follow-up [36]. For the enumerated reasons, statins should be employed as an element of standard therapy in heart transplant recipients [32, 39].

**Adverse effects of statins**

The most frequent adverse effects of statins consist in their influence on skeletal muscles and liver function. Statins may cause myopathy, myositis, or rhabdomyolysis, which may, in turn, result in acute kidney injury [11, 39, 40]. Toxic liver disease may also develop, expressed by increased transaminase activity in serum [41]. Other potential adverse effects include autoimmune conditions, dysrhythmias, conduction disorders, as well as gastrointestinal and urinary tract dysfunctions of various intensity [42]. Susceptibility to the occurrence of adverse effects is the highest among patients treated with large doses of statins, elderly patients, as well as individuals receiving medication metabolized by cytochrome P450 3A4 (CYP3A4), which is also responsible for the metabolism of some statins [11, 13].

**Interactions with other agents**

Using statins concurrently with enzymatic CYP3A4 inhibitors (ciclosporin, macrolide antibiotics, azole antifungal agents, calcium channel blockers, fibrates, niacin, acetaminophen) leads to an increased risk of toxic liver disease and myopathy. Also noteworthy are the interactions between statins and agents acting as CYP3A4 inducers (rifampicin, phenytoin, phenobarbital, dexamethasone); they accelerate the metabolism of statins and reduce their effectiveness [43]. Adverse effects resulting from drug interactions are more often encountered in the case of lipophilic statins (simvastatin, lovastatin, atorvastatin) metabolized primarily by CYP3A4 than in the case of hydrophilic statins (fluvasstatin, pravastatin, rosuvastatin) using other metabolic pathways [39]. The most frequent adverse effects resulting from interactions between immunosuppressants and statins pertained to ciclosporin. Studies indicate that concurrent statin and ciclosporin treatment is associated with...
the effectiveness and safety of the conducted treatment. There are also cases of statin-treated patients in whom the introduction of antifungal ketoconazole therapy was associated with the occurrence of rhabdomyolysis [41]. It has been suggested that ciclosporin and gemfibrozil may increase the concentration of all statins through mechanisms independent of the P450 cytochrome. For this reason, statin interactions with these agents should warrant special attention. In order to minimize the risk of serious side effects, monitoring the levels of aminotransferases and creatine kinase is recommended [39].

Conclusions

In view of the presented studies, it appears that statins should be an integral part of standard therapy after heart transplantation (Table I). The clinical benefits of statin use after heart transplantation significantly exceed the risk of potential adverse effects, as demonstrated by numerous studies. Notwithstanding, when introducing statins into the treatment regimen, one should consider the possible drug interactions, especially in patients undergoing long-term therapy with many agents. It is also of fundamental importance to properly select the type and dose of statins in order to reduce the risk of adverse effects and increase the effectiveness and safety of the conducted treatment.

The role of statins in patients after heart transplantation
