ABSTRACT

The large-scale distribution of neutral hydrogen in the Universe will be luminous through its 21 cm emission. Here, for the first time, we use the auto-power spectrum of 21 cm intensity fluctuations to constrain neutral hydrogen fluctuations at $z \sim 0.8$. Our data were acquired with the Green Bank Telescope and span the redshift range $0.6 < z < 1$ over two fields totalling $\approx 41$ deg$^2$ and 190 h of radio integration time. The dominant synchrotron foregrounds exceed the signal by $\sim 10^3$, but have fewer degrees of freedom and can be removed efficiently. Even in the presence of residual foregrounds, the auto-power can still be interpreted as an upper bound on the 21 cm signal. Our previous measurements of the cross-correlation of 21 cm intensity and the WiggleZ galaxy survey provide a lower bound. Through a Bayesian treatment of signal and foregrounds, we can combine both fields in auto- and cross-power into a measurement of $\Omega_{H_1}\delta_{H_1} = [0.62_{-0.15}^{+0.23}] \times 10^{-3}$ at 68 per cent confidence with 9 per cent systematic calibration uncertainty, where $\Omega_{H_1}$ is the neutral hydrogen (H i) fraction and $\delta_{H_1}$ is the H i bias parameter. We describe observational challenges with the present data set and plans to overcome them.

Key words: galaxies: evolution – large-scale structure of universe – radio lines: galaxies.

1 INTRODUCTION

There is substantial interest in the viability of cosmological structure surveys that map the intensity of 21 cm emission from neutral hydrogen. Such surveys could be used to study large-scale structure (LSS) at intermediate redshifts, or to study the epoch of reionization at high redshift. Surveys of 21 cm intensity have the potential to be very efficient since the resolution of the instrument can be matched to the large scales of cosmological interest (Chang et al. 2008; Loeb & Wyithe 2008; Seo et al. 2010; Ansari et al. 2012b). Several experiments, including BAOBAB (Pober et al. 2013b), BAORadio (Ansari et al. 2012a), BINGO (Battey et al. 2012), CHIME$^1$ and TianLai (Chen 2012) propose to conduct redshift surveys from $z \sim 0.5$ to 2.5 using this method.

The principal challenges for 21 cm experiments are astronomical foregrounds and terrestrial radio frequency interference (RFI). Extragalactic sources and the Milky Way produce synchrotron emission that is three orders of magnitude brighter than the 21 cm signal. However, the physical process of synchrotron emission is known to produce spectrally smooth radiation, occupying few degrees of freedom along each line of sight. In the absence of instrumental effects, these degrees of freedom are thought to be separable from the signal (Liu & Tegmark 2011, 2012; Shaw et al. 2013). RFI can be minimized through site location, sidelobe control and band selection. In the Green Bank Telescope (GBT) data analysed here, RFI is not found to be a significant challenge or limiting factor.

Subtraction of synchrotron emission has proven to be challenging in practice. Instrumental effects such as passband calibration and polarization leakage couple bright foregrounds into new degrees of freedom that need to be removed from each line of sight to reach the level of the 21 cm signal. The spectral functions describing these systematics cannot all be modelled in advance, so we take an empirical approach to foreground removal by estimating dominant
modes from the covariance of the map itself. This method requires more caution because it also removes cosmological signal, which must be accounted for.

Large-scale neutral hydrogen fluctuations above redshift \( z = 0.1 \) have been unambiguously detected only in cross-correlation with existing surveys of optically selected galaxies (Lah et al. 2009; Chang et al. 2010; Masui et al. 2013). Here, residual 21 cm foregrounds boost the errors, but do not correlate with the optical galaxies. The density fluctuations traced by survey galaxies may not correlate perfectly with the emission of neutral hydrogen, so their cross-correlation can be interpreted as a lower limit on the fluctuation power of 21 cm emission.

Several efforts have used the 21 cm line to place upper bounds on the reionization era (Bebbington 1986; Bowman & Rogers 2010; Paciga et al. 2013; Pober et al. 2013a) and \( z \approx 3 \) (see e.g. Subrahmanyan & Anantharamaiah 1999; Wieringa, de Bruyn & Katgert 1992) without the need to cross-correlate with an external data set. This is the first work to describe similar bounds for \( z \approx 0.8 \), using two fields totalling \( \approx 41 \text{deg}^2 \) and 190 h of radio integration time with GBT. Unlike the bounds from reionization, for which there is currently no cross-correlation, we are able to combine the auto- and cross-powers in a novel way, making a Bayesian inference of the amplitude of neutral hydrogen fluctuations, parametrized by \( \Omega_{\text{HI}}h^2 \). Throughout, we use cosmological parameters from Komatsu et al. (2009).

2 OBSERVATIONS AND ANALYSIS

The analysis here is based on the same observations used for the cross-correlation measurement in Masui et al. (2013). We flag RFI in the data, calculate 3D intensity map volumes, clean foreground contamination and estimate the power spectrum. Here, we will summarize essential aspects of the observations and analysis in Masui et al. (2013), and describe the auto-power analysis in more detail.

Observations were conducted with the 680–920 MHz prime-focus receiver at the GBT, sampled from 700 MHz (\( z = 1 \)) to 900 MHz (\( z = 0.58 \)) in 256 uniform spectral bins. The analysis here uses a 105 h integration of a 4.5 \( \times \) 2.4 h ‘deep’ field centred on 14\(^\text{h} \) 3\(^{\text{m}} \) 28\(^{\text{s}} \)5 right ascension, and an 84 h integration on a 7.0 \( \times \) 4.3 h ‘wide’ field centred on 0\(^{\text{h}} \) 52\(^{\text{m}} \)0\(^{\text{s}} \)0 right ascension, and 2\(^{\text{d}} \)9 declination.

The beam full width at half-maximum at 700 MHz is 0.314 and at 900 MHz it is 0.250. At band-centre, the beam width corresponds to a comoving length of 9.6 \( h^{-1} \) Mpc. Both fields have nearly complete angular overlap and good redshift coverage with the WiggleZ Dark Energy Survey (Drinkwater et al. 2010). Our absolute calibration is determined from radio point sources and is accurate to 9 per cent (Masui et al. 2013). For clarity, this remains as a separately quoted systematic error throughout, and plotted posterior distributions are based on statistical errors only.

2.1 Foreground cleaning

In this section, we develop the map cleaning formalism and discuss its connection to survey strategy. We begin by packing the three-dimensional map into an \( N_s \times N_s \) matrix \( M \) by unwrapping the \( N_s \) RA, Dec. pointings. For the moment, we ignore thermal noise in the map. The empirical \( v - v' \) covariance of the map is \( C = MM^T/N_s \), and it contains both foregrounds and 21 cm signal. This can be factored as \( C = U \Lambda U^T \), \( \Lambda \) is a diagonal matrix and is sorted in descending value. From each line of sight, we can then subtract a subset of the modes \( U \) that describe the largest components of the variance through the operation \( (1 - USU^T)M \), where \( S \) is a selection matrix with 1 along the diagonal for modes to be removed and 0 elsewhere.

In reality, \( M \) also contains thermal noise. To minimize its influence on our foreground mode determination, we find the noise-inverse-weighted cross-variance of two submaps from the full season of observing. Here, \( C_{AB} = (W_A \circ M_A)(W_B \circ M_B)^T/N_v \), where \( A \) and \( B \) denote subseason maps, \( W_A \) is the noise-inverse-variance weight per pixel of map \( A \) (neglecting correlations) and \( \circ \) is the element-wise matrix product. \( C_{AB} \) is no longer symmetric, and we take its singular value decomposition (SVD) instead, using the left and right singular vectors to clean maps \( A \) and \( B \), respectively. The weights are calculated in the noise model developed in the map-maker, but roughly track the map’s integration depth and weight against RFI. The weight is nearly separable into angle (through integration time) and frequency (through \( T_{\text{sys}}(v) \)), but we average to make it formally separable and so rank-1, so that it does not increase the map rank. The weighted removal for map \( A \) becomes \( (1/W_A) \circ (1 - U_SU^T)W_A \circ M_A \), where 1/Wi is the element-wise reciprocal.

Our empirical approach to foreground removal is limited by the amount of information in the maps. The fundamental limitation here surprisingly is not from the number of degrees of freedom along the line of sight, but is instead the number of independent angular resolution elements in the map (Nityananda 2010). To see why this is the case, notice that in the absence of noise our cleaning algorithm is equivalent to taking the SVD of the map directly: \( M = USV^T \) and thus \( C \propto MM^T = USU^TS \), with the same set of frequency modes \( U \) appearing in both decompositions. The rank of \( C \) coincides with the rank of \( M \) and is limited by the number of either angular or frequency degrees of freedom.

Assuming that the foreground maps have comparable spurious overlap with the signal, one arrives at a transfer function rule of thumb \( T = P_{\text{sig out}}/P_{\text{sig in}} \sim \sim (1 - N_\text{res}/N_\text{in})(1 - N_\text{res}/N_\text{in})^{T/2} \), where \( N_\text{in} \) is the number of modes removed, \( N_\text{res} = 256 \) is the number of frequency channels and \( N_\text{res} \) is the number of resolution elements (roughly the survey area divided by the beam solid angle). A limited number of resolution elements can greatly reduce the efficacy of the foreground cleaning at the expense of signal.

The noise-weighted effective areas of the wide and deep fields are \( \sim 8 - 3 \text{deg}^2 \), giving roughly 70 and 30 independent resolution elements at the largest beam size. The rank of \( C \) is then less than the number of available spectral bins in both cases. To recover a factor of roughly 2 to 3 in the number of resolution elements in the weighted \( v - v' \) covariance, all pointings with weights above the median are reweighted equally.

The optimal number of modes to remove coincides with the most stringent upper bound from the auto-power spectrum. For too few modes removed, the bound is limited by residual foregrounds, and for too many modes removed, it is limited by signal loss and increasing error bars. The wide field has a clear minimum from 20 to 30 modes, and we remove 30. This optimum concerns an ensemble average of surveys, and a particular treatment in one survey may scatter lower. Hence, while the deep field has a minimum at 15, we conservatively remove 10.

2.2 Instrumental systematics

The physical mechanism of synchrotron radiation suggests that it is described by a handful of smooth modes along each line of sight (Liu & Tegmark 2012). Instrumental response to bright foregrounds,
however, can convert these into new degrees of freedom. An imperfect and time-dependent passband calibration will cause intrinsically spectrally smooth foregrounds to occupy multiple modes in our maps with non-trivial spectral structure. We control this using a pulsed electronic calibrator, averaged for each scan.

We believe that the most challenging spectral structure from foregrounds is caused by leakage of polarization into intensity. Here, each Mueller matrix element has a characteristic beam on the sky, dependent on offset from the boresight and frequency. The spectral structure converts spectrally smooth polarization into new degrees of freedom. Faraday rotation of the polarization introduces further spectral degrees of freedom.

The leakage beam is optical in origin, mixes \(\sim 10\) per cent of polarization to intensity, is antisymmetric about the boresight to a good approximation and is slightly broader than the primary beam. In addition, the frequency dependence of the pure Stokes I beam mixes spatial into spectral structure. We mitigate both of these terms by convolving to a common resolution corresponding to 1.4 times the beam size at 700 MHz (the largest beam). This convolution is based on a frequency-dependent beam model from source scans. Such a convolution is viable because GBT has roughly twice the resolution needed to map LSS in the linear regime. However, this convolution reduces the number of independent resolution elements in the map by a factor of 2, increasing the challenges discussed in Section 2.1.

The present results are limited largely by the area of the regions and our understanding of the instrument. With a factor of roughly 10 more than the present area, the resolution could be degraded at less expense to the signal. This requires significant telescope time because the area must also be covered to roughly the same depth as our present fields. It would however provide a significant boost in overall sensitivity for scientific goals such as measurement of the redshift-space distortions. In addition, we are investigating map making that would unmix polarization using the Mueller matrix of beams, as determined from source scans.

### 2.3 Power spectrum estimation

Our starting point for power spectral estimation is the optimal quadratic estimator described in Liu & Tegmark (2011). To avoid the thermal noise bias, we only consider cross-powers between four adjacent \(k\)-bins. Powers in their two-dimensional Gaussian inverse noise variance \(N(\mathbf{k}) = P(\mathbf{k})^2/P_{\text{auto}}(\mathbf{k})^2\), where \(P_{\text{auto}}(\mathbf{k})\) is the average of \(\{P_{A,A}, P_{B,B}, P_{C,C}, P_{D,D}\}\) (pairs which contain the thermal noise bias) and \(N(\mathbf{k})\) is the number of three-dimensional \(k\) modes that enter a two-dimensional bin \(k_1, k_2\). In addition to the Gaussian noise weights, we impose two additional cuts in the two-dimensional \(k\)-power. For \(k_1 < 0.035 \text{ h Mpc}^{-1}, k_2 < 0.08 \text{ h Mpc}^{-1}\) for the deep field and \(k_1 < 0.04 \text{ h Mpc}^{-1}\) for the wide field, there are few harmonics in the volume, resulting in strips in the two-dimensional power spectrum where the errors are poorly estimated and strongly correlated. For \(k_1 > 0.3 \text{ h Mpc}^{-1}\), the instrumental resolution produces significant signal loss, so this is also truncated.

Foregrounds in the input maps and the 21 cm signal itself are non-Gaussian, but after cleaning, the thermal noise dominates both contributions in an individual map, and Gaussian errors (see e.g. Das et al. 2011) provide a reasonable approximation. These take as input the auto-power measurement itself (for sample variance) and \(P_{A,A}\) terms that represent the thermal noise. Sample variance is significant only in the deep field in the lower 1/3 of the reported wavenumbers. Gaussian errors agree with the standard deviation of the six cross pairs that enter the spectral estimation in the regime where sample variance is negligible.

The finite survey size and weights result in correlations between adjacent \(k\)-bins. We apodize in the frequency direction using a Blackman window and in the angular direction using the map weight itself (which falls off at the edges due to scan coverage). The bin–bin correlations are estimated using 3000 signal plus thermal noise simulations assuming \(T_{\text{sys}} = 25\) K. To construct a full covariance model, these are then recalibrated by the outer product of the Gaussian error amplitudes for the data relative to the thermal noise simulation errors.

The Bayesian method developed in the next section assumes that adjacent bins are uncorrelated. To achieve this, we take the matrix square root of the inverse of our covariance model matrix and normalize its rows to sum to one. This provides a set of functions which decorrelate (Hamilton & Tegmark 2000) the pre-whitened power spectrum and boosts the errors. At large scales \((k = 0.1 \text{ h Mpc}^{-1})\) where these effects are relevant, decorrelation and sample variance increase the errors by a factor of 1.5 in the wide field and 4 in the deep field.
3 RESULTS

The auto-power spectra presented in Fig. 1 will be biased by an unknown positive amplitude from residual foreground contamination. These data can then be interpreted as an upper bound on the neutral hydrogen fluctuation amplitude, $\Omega_{\text{HI},b_{\text{HI}}}$. In addition, we have also measured the cross-correlation with the WiggleZ galaxy survey (Masui et al. 2013). This finds $\Omega_{\text{HI},b_{\text{HI}},r} = [0.43 \pm 0.07 \text{ (stat.)} \pm 0.04 \text{ (sys.)}] \times 10^{-3}$, where $r$ is the WiggleZ galaxy–neutral hydrogen cross-correlation coefficient (taken here to be independent of scale). Since $|r| < 1$ by definition and is measured to be positive, the cross-correlation can be interpreted as a lower bound on $\Omega_{\text{HI},b_{\text{HI}}}$. In this section, we will develop a posterior distribution for the 21 cm signal auto-power between these two bounds, as a function of $k$. We will then combine these into a posterior distribution on $\Omega_{\text{HI},b_{\text{HI}}}$.

The probability of our measurements given the 21 cm signal auto-power and foreground model parameters is

$$p(d_k | \theta_k) = p(d_k | s_k, r) p(d_k | s_k, f_{\text{deep}}) p(f_{\text{wide}} | s_k, f_{\text{deep}}).$$  (2)$$

Here, $d_k = [d^r_k, d^{\text{deep}}_k, d^\text{wide}_k]$ contains our cross-power and deep and wide field auto-power measurements, while $\theta_k = [s_k, r, f^\text{deep}_k, f^\text{wide}_k]$ contains the 21 cm signal auto-power, cross-correlation coefficient, and deep and wide field foreground contamination powers, respectively. The cross-power variable $d^r$ represents the constraint on $\Omega_{\text{HI},b_{\text{HI}},r}$ from both fields and the range of wavenumbers used in Masui et al. (2013). The band-powers $d^\text{deep}_k$ and $d^\text{wide}_k$ are independently distributed following decorrelation of finite-survey effects. We assume that the foregrounds are uncorrelated between $k$-bins and fields, also. This is conservative because knowledge of foreground correlations would yield a tighter constraint. We take $p(d^r | s_k, r)$ to be normally distributed with mean proportional to $r \sqrt{\Omega_1}$, and $p(d^\text{deep}_k | s_k, f_{\text{deep}})$ to be normally distributed with mean $s_k + f_{\text{deep}}$ and errors determined in Section 2.3 (and analogously for the wide field). Only the statistical uncertainty is included in the width of the distributions, as the systematic calibration uncertainty is perfectly correlated between cross- and auto-power measurements and can be applied at the end of the analysis.

We apply Bayes’ theorem to obtain the posterior distribution for the parameters, $p(\theta_k | d_k) \propto p(d_k | \theta_k) p(s_k) p(r) p(f^\text{deep}_k) p(f^\text{wide}_k)$. For the nuisance parameters, we adopt conservative priors. $p(f^\text{deep}_k)$ and $p(f^\text{wide}_k)$ are taken to be flat over the range $0 < f_k < \infty$. Likewise, we take $p(r)$ to be constant over the range $0 < r < 1$, which is conservative given the theoretical bias towards $r \approx 1$. Our goal is to marginalize over these nuisance parameters to determine $s_k$. We choose the prior on $s_k$ to be flat, which translates into a prior $p(\Omega_{\text{HI},b_{\text{HI}}} | \Omega_{\text{HI},b_{\text{HI}},r})$. The signal posterior is

$$p(s_k | d_k) = \int p(s_k, r, f^\text{deep}, f^\text{wide} | d_k) \, dr \, df^\text{deep}_k \, df^\text{wide}_k. $$  (3)$$

This involves integrals of the form $\int_0^1 p(d^r | s_k, r) \, dr$ which, given the flat priors that we have adopted, can generally be written in terms of the cumulative distribution function of $p(d^r | s_k, r)$. Fig. 2 shows the allowed signal in each spectral $k$-bin.

Taking the analysis further, we combine band-powers into a single constraint on $\Omega_{\text{HI},b_{\text{HI}}}$. Following Masui et al. (2013), we consider a conservative $k$-range where errors are better estimated $(k > 0.12 \text{h Mpc}^{-1})$ to avoid edge effects in the decorrelation operation) and before uncertainties in non-linear structure formation become significant $(k < 0.3 \text{h Mpc}^{-1})$. Fig. 3 shows the resulting posterior distribution.

Our analysis yields $\Omega_{\text{HI},b_{\text{HI}}} = [0.62^{+0.23}_{-0.15}] \times 10^{-3}$ at 68 per cent confidence with 9 per cent systematic calibration uncertainty. The range of allowed $\Omega_{\text{HI},b_{\text{HI}}}$ is bracketed by the cross- and auto-power
measurements, and is a robust statement. The peak of the posterior between these bounds is sensitive to the prior choice, and so the quoted posterior should be interpreted in the context of our prior choices here. Another reasonable signal prior is that $P(O_{b1}|b_{HI})$ is flat, which shifts the central value by $\sim 10$ per cent. Note that we are unable to calculate a goodness of fit to our model because each measurement is associated with a free foreground parameter which can absorb any anomalies.

4 DISCUSSION AND CONCLUSIONS

Through the measurement of the auto-power, we extend our previous cross-power measurement of $O_{b1}|b_{HI}$ (Masui et al. 2013) to a determination of $O_{b1}|b_{HI}$. This is the first constraint on the amplitude of 21 cm fluctuations at $z \sim 0.8$, and it circumvents the degeneracy with the cross-correlation $r$. The 21 cm auto-power yields a true upper bound because it derives from the integral of the mass function. In the future, redshift distortions (Wyithe 2008; Masui, McDonald & Pen 2010) can be used to further break the degeneracy between $b_{HI}$ and $O_{b1}$, and complement challenging $Hubble Space Telescope$ measurements of $O_{HI}$ (Rao, Turnshek & Nestor 2006). Our present survey is limited by area and sensitivity, but we have shown that foregrounds can be suppressed sufficiently, to nearly the level of the 21 cm signal, using an empirical mode subtraction method. Future surveys exploiting the auto-power of 21 cm fluctuations must develop statistics that are robust to the additive bias of residual foregrounds and that control instrumental systematics such as polarized beam response and passband stability.

ACKNOWLEDGEMENTS
