Changes in pain, swelling, and range of motion according to physical therapy intervention after total knee arthroplasty in elderly patients

Eun-Kyung Noh, Chang-Sik An

Department of Physical Therapy, Eulji University, Seongnam, Republic of Korea

Objective: This study was carried out to compare changes in pain, swelling and range of motion (ROM) between the two groups according to physical therapy intervention.

Design: Randomized controlled trial.

Methods: There were a total of 20 elderly subjects ages 65-75 years old who have been admitted to the hospital for a total knee arthroplasty. After surgery, the experimental group (n=10) carried out quadriceps femoris muscle strengthening exercise, hamstring stretching exercises and gastrocnemius stretching exercise with a physical therapist for 30 minutes and additionally, received ice pack therapy for 20 minutes once a day. The control group (n=10) carried out continuous passive motion for 30 minutes and received ice pack therapy for 20 minutes once a day. The experimental group and control group carried out each intervention program for 2 weeks 3 times a week. The Visual Analogue Scale was used to assess pain, tape measurements were taken to assess swelling, and a steel goniometer was used to assess knee joint ROM.

Results: As a result, the experimental group showed a statistically significant decrease in the pain and swelling, and a significant increase in knee flexion ROM after the intervention, compared to the control group (p<0.05). There was a significant improvement in pain, edema, and knee flexion and extension ROM in all subjects after intervention (p<0.05).

Conclusions: According to the results of this study, exercise in the experimental group is effect on the pain, swelling and ROM for total knee arthroplasty.

Key Words: Exercise, Pain, Range of motion, Total knee arthroplasty

Introduction

Osteoarthritis, the most common form of arthritis, is a degenerative joint disease that causes chronic pain, stiffness, and disability [1], and bone invasion occurs primarily in 80% of those 55 years or older with a higher prevalence rate in females than in males [2]. Saxon et al. [3] reported that the site of invasion in arthritis can involve any joint; however, the knee joint has the highest rate of occurrence [4]

A normal knee joint consists of smooth cartilage, allowing the cartilage to move with almost no friction. However, a damaged joint facet is rough and irregular, which can cause excruciating pain. Moreover, exacerbation of arthritis can lead to joint deformation and stiffness. A total knee arthroplasty (TKA) is performed to address these problems [5].

Han [6] reported that TKA, as a procedure that replaces the damaged joint facet with an artificial structure similar to the knee joint, After a TKA, the functional status of the body is severely degraded due to the reduced strength and joint range of motion (ROM) and extreme pain caused by the surgery. It calls for exercise programs for enhancing the functional status, especially for seniors. They are likely to have many severe complications after a surgery [7].

Naso et al. [8] indicated that after TKA, muscle strength
can be reduced from the incision of the quadriceps, which plays an important role in lower-extremity function, and even more severe pain can develop. On the other hand, Stevens et al. [9] reported that if the quadriceps fails to recover within the first month after surgery, the patient will experience persistent weakening of the muscles. Therefore, early implementation of muscle strengthening exercises for the quadriceps is one of the important factors that determine the success of TKA [10].

Recovery of muscle strength in the quadriceps is very important for weight bearing, stability, and normal functioning of the knee joints [11,12]. Quadriceps setting exercise (QSE) is one of the primary muscle strengthening exercises designed for early muscle strengthening, through the isometric contraction of the quadriceps in patients who have postoperative knee joint dysfunction. In a study that compared QSE with electrical stimulation, it was reported that QSE was more effective in increasing muscle strength [13].

According to studies on continuous passive motion (CPM), CPM extends the ROM in the joints in the early stages after surgery [14]. However, CPM has the disadvantages of requiring a lengthy treatment period and high costs associated with equipment requirements. Furthermore, there have been reports on CPM causing postoperative pain and discomfort in some patients [15].

Edema that develops at the surgical site after TKA often occurs during early stage of the surgery. In severe cases of edema, blisters can form and damage the skin; early ambulation can be hindered, thus delaying recovery; and pain from edema may occur when starting rehabilitation [16]. Cold therapy is known to induce the contraction of peripheral blood vessels, which, in turn, reduces the temperature in the damaged area. Through this mechanism, edema is controlled through the lowering of cellular permeability, hemorrhaging, and tissue metabolism; in addition, it has the effect of changing the pain transmission from the damage muscle and reducing muscle contraction as a response to such change [17].

Cold therapy is widely used in clinical settings owing to its cost-effectiveness, relative safety, and ease of use compared with other interventions. However, the application of cold therapy on TKA patients has been limited to only a few cases. As there is a lack of studies on the effects of cold therapy on edema, such studies are needed in TKA patients by using cold therapy that has been proven to be effective in alleviating edema. Based on the theories above, this study intends to solve the medical issues of the patients who undergo TKA more effectively. First, ice packs were applied in order to reduce their swelling. As for the experimental group, they engaged in quadriceps femoris muscle strengthening and hamstring and gastrocnemius stretching exercises in a systematic manner. There is a need to verify the effects in a short period of time in comparison with the CPM applied to the control group.

Therefore, the objective of the present study was to investigate the changes in pain, edema, and ROM in the knee joints of elderly patients according to the post-TKA physical therapy intervention modality, and to use the findings to provide basic data for deciding the intervention modalities and application period for TKA patients.

**Methods**

**Study subjects**

The present study was conducted after receiving the consent form for study participation from the subject or the subject’s guardian after sufficient explanation on the study content and objectives was given. The subjects consisted of 20 elderly patients, 65-75 years old, who had concomitant pain and edema, and were hospitalized to undergo TKA at Eulji General Hospital in Nowon district of Seoul, South Korea, between May 4 and June 26, 2015. The criteria for selecting the subjects are as follows. First, those who have received a TKA within the last week. Second, those who have more than a moderate level of pain (visual analogue scale [VAS] 5) on the lower limbs. Third, those who have no medical conditions other than an osteoarthritis on the lower limbs.

**Study design**

The present study was conducted on patients with a diagnosis of degenerative knee osteoarthritis and hospitalized to undergo TKA, with 10 patients each assigned to the experimental group and the control group. On day 1, the control group performed 30 minutes of CPM, followed by 20 minutes of ice packing, whereas the experimental group performed 30 minutes of hamstring stretching, gastrocnemius muscle stretching, and quadriceps femoris muscle strengthening exercises with a physical therapist, followed by 20 minutes of ice packing. The intervention programs for the experimental and control groups consisted of three sessions per week for 2 weeks. A total of three measurements were taken before the intervention and at days 7 and 14 of after the intervention.
Physical therapy intervention method for the control group

**CPM**

CPM (CPS-1000 Stratek; State Korea, StráTek, Anyang, Korea) was performed with the subject in a supine position, and the passive motion consisted of a single cycle of flexion and extension with a speed of 30 seconds per cycle with the movement maintained at that speed. The CPM was set at a motion within a range that did not cause pain to the patient [18].

**Ice pack**

An ice pack was applied directly to the affected area for 20 minutes with the patient in a supine position (Figure 1).

Physical therapy intervention method for the experimental group

**Hamstring stretching exercise**

Straight leg raising was performed by the subject by raising the operation leg from the floor while in a supine position. The therapist’s hand held the non-operated leg to prevent it from being lifted (Figure 2) [18].

**Quadriceps femoris muscle strengthening exercise**

1. The subject, while in a supine position, lifted the heel

---

**Figure 1.** Ice pack.

**Figure 2.** Hamstring stretching exercise.

**Figure 3.** Quadriceps femoris muscle strengthening exercise-1.

**Figure 4.** Quadriceps femoris muscle strengthening exercise-2.
Gastrocnemius muscle stretching exercise

In a standing position, the subject placed the front portion of the sole on top of a wedge and performed the exercise while focusing on flexing the hip and knee joints (Figure 5) [18].

Ice pack

Ice pack was applied directly to the affected area for 20 minutes with the patient in a supine position (Figure 1).

Measurement methods

After applying the physiotherapy intervention to the control group and experimental group, their pain, swelling, and joint ROM were measured as follows.

Pain measurement

Pain was measured by using a 10 cm horizontal VAS, with the left end representing ‘no pain’ (0 point) and the right end representing ‘very severe pain’ (10 points). The subject marked the pain felt on the scale with an arrow. A higher score indicated a greater pain severity. The data analysis revealed that the intertester reliability (r=0.62; intraclass correlation coefficient [ICC]=0.75) were high [19].

Edema measurement

In the present study, edema was quantified according to the changes in the circumference of the lower extremity. For this evaluation, a tape measurement method that is commonly used to evaluate an increase in lower extremity volume was used. To reduce measurement errors, the mean value from three repeated measurements was used.

The measurement method involved using a double-sided tape measure with width of 10 mm and a length of 150 m (60 in) to measure the circumference of the area 5 cm above the knee joint line, while the subject was in a supine position [20].

Joint angle measurement

The ROM of the knee joint of the subject was measured by using a steel goniometer (Steel Goniometer Stainless, BaseLine; Patterson Medical, Warrenville, IL, USA). To reduce measurement errors, the mean value from three repeated measurements was used.

To measure the flexion and extension angles of the knee joint, the subject was placed in a supine position, and the maximum degree of flexion and extension was measured with the fixed arm placed in between the greater trochanter of the femur and the middle portion of the femur, and the moving arm positioned in a straight line from the fibular head to the lateral malleolus of the ankle. The data analysis revealed that the intertester reliability (r=0.98; ICC=0.99) were high [21].

Data analysis

Statistical analyses of the measured data in the present study were performed by using the Windows version of PASW ver.18.0 (IBM Co., Armonk, NY, USA). An independent t-test was used for the intergroup comparison of the differences in knee joint pain, edema, and ROM. For the intergroup comparison of the pattern of change in knee joint pain, edema, and ROM, a one-way repeated ANOVA that has a between-subjects factor was used. The statistical significance level was set at α=0.05.
Results

General characteristics of the subjects

Among the subjects, there were 7 males and 13 females, with a mean age of 68.6 years. The mean height and weight was 164.1 cm and 61.1 kg, respectively, and six subjects had received a TKA on the left side, whereas 14 had received a TKA on the right side. The general characteristics of the experimental and control groups are given in Table 1.

Intergroup comparison on level of pain

Analyses were performed to examine how the differences in pain levels changed according to the measurement period (Table 2). Although there were no significant intergroup differences at pre-intervention and at day 7 of the intervention, a significant intergroup difference was found on day 14 of the intervention \((p<0.001)\). Therefore, it can be stated that pain according to the time was different between the two groups \((p<0.001)\).

Intergroup comparison on the level of edema

Analyses were performed to examine how the differences in pain changed according to the measurement period (Table 2). Although there were no significant intergroup differences at pre-intervention and on day 7 of the intervention, a significant intergroup difference was found on day 14 of the intervention \((p<0.05)\). Therefore, it can be stated that the level of edema was different between the two groups according to the time period \((p<0.001)\).

Values are presented as mean (SD).
Bruun-Olsen et al. [15] in which providing CPM after TKA had no positive effect when compared with applying only active movement for pain, ROM, and gait ability at the first week and 3 months after surgery. Moreover, Han [6] applied a ground rehabilitation program with three sessions per week for 6 weeks, and reported a significant reduction in pain, similar to the results from previous studies. Therefore, it was determined that the exercise program applied to the experimental group in the present study had a positive effect on pain reduction.

In general, edema develops early in surgery, and consequently, patients complain of pain and discomfort from edema when starting an early rehabilitation program [16,25]. Accordingly, cold therapy is considered an effective treatment method resulting in a speedy recovery and the alleviation of edema and pain in the patients. Therefore, in the present study, we applied cold therapy on both groups for the reduction of edema and pain. As a result, both groups showed a significant reduction in edema over time, measured on the basis of the leg circumference at 5 cm above the knee. However, there was no significant intergroup difference at pre-intervention and on day 7 of the intervention, whereas a significant intergroup difference was observed on day 14 of the intervention. The findings in the present study were consistent with the results from the study by Chesterton et al. [26], in which the exercise program and cold therapy applied to the experimental group were shown to be effective in reducing edema and pain.

In the present study, examination of the effects on ROM between the two groups according to time showed a significant increase in ROM in both groups as time elapsed. Although there was no significant intergroup difference at pre-intervention, significant intergroup differences were found on day 7 and day 14 of the intervention. These findings were consistent with precedent studies that reported that CPM, as compared to active exercise, had no effect on the ROM at 1 week after surgery [14,27,28]. These results therefore show that an exercise program applied to the experimental groups was more effective than CPM in increasing the flexion angle within a short period time. Although both groups showed the extension ROM reaching the normal ROM level at day 14 of the intervention, there was no significant intergroup difference compared to that at pre-intervention.

As shown above, improvements in pain, edema, and ROM over time were seen in both groups of elderly patients according to the intervention method used after TKA. In comparison to pre-intervention, significant differences in pain, edema, and flexion ROM were seen in the experimental group compared with those in the control group, at 2 weeks after intervention. Moreover, improvements in the extension ROM were seen in both groups at 2 weeks after the intervention, as compared to that at pre-intervention; however, the difference was not significant.

The limitations of this study are as follows. First, there was a small number of subjects. Second, the exercise period was not long enough, because most patients are released from a university hospital within 3 weeks. Third, the experiment was conducted in one hospital only and thus it is problematic to expand the findings for broader interpretation.

The present study was a quasi-experimental research that used a one-way repeat ANOVA to test the mean differences between the experimental and control groups with regard to measurements of pain, edema, and ROM, taken at pre-intervention and on day 7 and day 14 of the intervention after applying an exercise program on elderly patients who were hospitalized to receive TKA for degenerative knee osteoarthritis, with the program starting from postoperative day 4 and lasting for 2 weeks.

The results showed that in the comparisons between the experimental and control groups, reduction in pain and edema was seen according to the elapsed time, whereas flexion ROM showed a significant increase. Moreover, improvements in the extension ROM were seen in both groups over time, as compared with that immediately after surgery; however, the improvement in the experimental group was greater than that in the control group. Nevertheless, the difference between the two groups was not significant.

On the basis of the above results, it was determined that implementation of an exercise program immediately after surgery was effective for improving physical functions in TKA patients. Therefore, systematically applying stretching and muscle strengthening exercises on TKA patients immediately after surgery can assist to a more timely return to independent daily living.
