Intracranial infections include a wide range of different medical conditions, each with unique clinical, radiological, and surgical characteristics. Many of these conditions progress rapidly and result in significant morbidity and mortality if appropriate diagnostic and therapeutic procedures are not initiated. Our study is focused on intracerebral (brain) abscesses and subdural empyemas, which are the most surgically treated intracranial infections.

A brain abscess is a focal pyogenic infection of the brain’s parenchyma. It has a typical capsule formation and purulent material inside the capsule. Brain abscesses may be solitary lesions or present as multiple intracranial foci. The most frequent locations are the frontotemporal, frontoparietal, parietal, and occipital lobes and the cerebellum. Although brain abscesses are mostly seen in adults, they may also present in childhood. Major predisposing factors for the development of a brain abscess are a close infection focus, hematogenous spread from a distant focus, and previous trauma. The microbiological etiology of the abscess depends on many factors such as the site of primary infection, a patient’s age and immunological condition, underlying diseases, and the geographic location of the patient.

Subdural empyema is also a pyogenic infection but is located between the dura and arachnoid materes. It is an
uncommon condition, representing 15%–20% of confined intracranial diseases. The most common cause is a previous neurosurgical procedure, such as tumor or subdural hematoma surgery. Sinusitis and otogenic infections are the other etiological factors. Previous skull trauma and meningitis may also be responsible for subdural empyemas.

CT scanning and MRI are the two primary radiological modalities used for the detection of intracranial infections. While CT scanning is widely available and very useful for rapid diagnosis and assessment of hydrocephalus, mass lesions, hemorrhage, or brain edema, MRI is often required to detect more subtle findings. MRI is more sensitive, especially for evaluating CSF involvement, leptomeningitis, empyema, ventriculitis, vasculitis, and abscess. Metastatic brain tumors and radiation necrosis are the most common conditions in the differential diagnosis of intracranial infections.

Current surgical treatment methods include craniotomy for resection or stereotactic aspiration of the abscess material. In most instances, drainage of the purulent material is enough to initiate healing of the intracranial infection. In addition, there is no significant difference between excision and drainage alone in terms of patient morbidity and mortality. However, excision is better than aspiration with regard to duration of antibiotic use, length of hospital stay, and overall cost of treatment. Endoscopic approaches are being used for deep-seated abscesses. Resection using craniotomy is usually the preferred technique for large, multiple abscesses causing mass effect or superficial lesions located in noneloquent brain regions. Stereotactic aspiration is reserved for deep-seated abscesses or those located within or adjacent to eloquent regions.

We conducted a retrospective review of the intracranial infections treated in our department over the past 10 years. We focused on patients with brain abscess or subdural empyema who underwent surgical intervention. Surgical techniques and postoperative outcomes in particular are presented and discussed.

**Methods**

This is a retrospective study from a neurosurgery department of a tertiary university hospital. Fifty-two patients with intracranial infection (brain abscess or subdural empyema) underwent surgical treatment between 2008 and 2018. Eleven patients were female, and 41 (79%) patients were male. The mean age was 40.46 years (range 10–75 years). MRI was used for the diagnosis and follow-up of all patients. The surgical strategy was designed based on the radiological characteristics of each case. The important part of our surgical technique was removal of the abscess wall either partially or totally, if possible. Small abscesses were removed en bloc once the cleavage plane was identified, while large abscesses were drained before
a secure plane was found to limit the risks of damage to the surrounding brain tissue. Craniotomy was preferred for subdural empyema and most of the brain abscesses. It was used to reach and expose the entire wall of the brain abscess. Some abscess walls were rigid and dense, while the others were thin and difficult to dissect from the cortex. Patients in early or late cerebritis stages had very thin abscess walls. In these cases, the surgical pathway was designed to extend the exposure of the abscess wall, with special attention to the surrounding vascular and neural structures (Fig. 1). Cerebral sulci close to the cerebral abscess were used for exposure of the abscesses. A neuro-navigation system was used to provide easy access to deep abscesses and drainage of the infection material with less invasive methods. However, we never performed drainage alone, and the abscess wall was always partially or totally removed during the surgery. This was the critical part of the procedure for the prevention of abscess recurrence and for differentiation of brain abscesses from tumor, especially brain metastases. Drainage of the entire infection material was not possible in some cases due to the deep location of the abscess, significant brain edema, or proximity to important neurovascular structures. In these cases, even if the abscess material could not be completely drained, some samples of the abscess wall were obtained for histopathological examination. In subdural empyema cases, craniotomy allowed a wide exposure, adequate exploration, and better evacuation of the purulent material (Fig. 2). It was easy to reach and evacuate the infection material via craniotomy. However, dissection and removal of the thick and adherent inner membrane was quite difficult. In most cases, the inner membrane was partially removed because of the risk of cortical damage (Fig. 1). The color of the material was also recorded for the differentiation of the abscess etiology, as green abscess material (Fig. 2), yellowish material, and white material may be indicators of different microorganisms (Figs. 3–5). Grayish material was observed in cases of necrosis, which was secondary to previous radiotherapy or malignant brain tumors such as glioblastoma.

Endoscopic navigation-based abscess drainage was performed in selected patients with deep-seated abscess. The neuronavigation system was used for all intracranial abscess cases. Etiology, clinical presentations, Glasgow Coma Scale score at admission, length of hospital stay, and culture results obtained were recorded for all patients.

This study was approved by the University of Health Sciences, Gulhane noninterventional research ethics committee.

Results

The characteristics of 52 patients are summarized in Table 1. Eighteen (35%) patients had intracerebral abscesses, and 34 had subdural empyemas. Sinusitis, previous cra-
niotomy, otorhinogenic infection (Fig. 3), and trauma (Fig. 6) were the common causes of intracranial infection in our series. No microbiological agent was isolated in 29 (56%) cases, while staphylococci species were isolated in 8 cases. Endoscopic navigation-based aspiration was performed in 3 cases (Fig. 7), and abscess removal via craniotomy was performed in 15 intracerebral abscess cases (Fig. 1). The mean length of hospital stay was 33.7 days (range 4–68 days) for patients with brain abscesses and 27.3 days (range 7–130 days) for patients with subdural empyemas. Three patients with abscesses died after surgery, and 1 patient died after subdural empyema drainage. Two of 3 abscess patients were immunocompromised; in addition, one had multiple *Aspergillus* abscesses and the other had a left thalamic abscess (Fig. 7). Both patients died within 1 week after surgery. The other 2 patients died of previously diagnosed malignant tumors within 1 year postoperatively. *Aspergillus* was detected in 2 brain abscess cases, and both of these patients had multiple abscesses (Fig. 4). Mucormycosis was isolated in 1 frontobasal brain abscess. Associated intracranial tumor was diagnosed in 2 patients with brain abscess. One was a chordoma (Fig. 5) and the other was an anaplastic astrocytoma.

**Discussion**

We presented 52 patients who underwent surgical treatment for intracranial infection. Eighteen (35%) of the patients had intracerebral abscesses while the remaining patients had subdural empyemas secondary to previous surgeries, implanted materials, and otogenic infections. Most of the patients were male, and most patients were between the ages of 18 and 39 years. Two patients had an intracranial tumor associated with the abscess. No etiological agent could be identified in 29 (56%) cases, while staphylococci species were the most common agents in our series. The mortality rate was 7.7%.

Otogenic brain abscess and meningitis are the most widely recognized focal complications of otitis media. Curiously, an otogenic brain abscess identified with otitis media is usually found nearby the temporal bone, mostly within the temporal lobe and cerebellum (Fig. 3). This area is additionally demonstrative of the principal mechanism of infection that advances through the osseous borders of temporal bone by means of osteitis and bony erosion. In these cases, the abscess can be drained through the transmastoid approach, avoiding an extra craniotomy. In our series, otorhinogenic infection was detected as the prima-
ry source in 8 patients. One of these 8 patients had a simultaneous cerebellar abscess and mastoiditis, and the patient underwent removal of abscess and drainage of the mastoiditis in the same session. We performed a suboccipital craniotomy and retrocerebellar approach to reach and remove the abscess. Then, the mastoid bone was drilled, and purulent material within the bone was drained (Fig. 3).

Differential diagnosis of brain abscesses is of paramount importance. Metastatic brain tumors and radiation necrosis are the most common conditions in the differential diagnosis. Dynamic susceptibility contrast-enhanced perfusion MRI, proton MR spectroscopy, and diffusion-weighted imaging can be used preoperatively to differentiate abscesses from glioblastomas and/or metastases.21,29 A brain abscess may be associated with or located within the brain tumor. This is a very rare occurrence, and only a few cases of abscess associated with intracranial tumor have been reported in the literature. The mortality of this combination is quite high. The most reported tumors coexisting with abscesses are glioblastomas, but meningiomas, astrocytomas, and metastases have also been reported.2,9,16,19,21 The exact pathophysiological basis of this coexistence is unknown, but immunodeficiency of the patients due to the immunosuppressive agents given for cancer treatment may contribute to the coexistence of abscess and metastasis.16 Another mechanism is that the tumor necrosis cavity may be a potential medium for an infection to develop.25 Moreover, if the tumor is close to the venous sinuses, hematogenous transmission of bacterial pathogens may be facilitated from the venous circulation to the tumor.6 Goto et al.16 reported a case of brain abscess within the cerebellar metastasis, and they emphasized the importance of considering coexisting diseases prior to surgery. They also showed the importance of abscess wall resection and examination for the accurate diagnosis. In our series, 2 patients had associated intracranial tumors. One had a chordoma and the other had a cystic anaplastic astrocytoma. The chordoma was closely associated with a frontal abscess, which were both removed during the same session (Fig. 5).

| Characteristic          | No. of Patients (%) |
|-------------------------|---------------------|
| Sex                     |                     |

GCS = Glasgow Coma Scale.
Bacteroides, Peptostreptococcus, and Streptococcus are mostly isolated in brain abscesses secondary to contiguous dissemination.\textsuperscript{4,10,25} Peptostreptococcus and Streptococcus (especially viridans streptococci and microaerophilic streptococci) are mostly identified in patients with a brain abscess due to cardiac disease.\textsuperscript{25} Staphylococcus and Streptococcus are found in patients who underwent previous surgical procedures. Staphylococcus, Streptococcus, Clostridium, and Enterobactericeae are seen in patients with open head trauma.\textsuperscript{4,22,25} Fungal infections, Toxoplasma, Staphylococcus species, Streptococcus species, and Pseudomonas are frequently observed in immunocompromised patients and after organ transplantation, chemotherapy, and steroid usage.\textsuperscript{4,20,25} Streptococcus anginosus is a commensal microbe of the mucosae of the oral cavity, gastrointestinal tract, and urogenital tract and is rarely found in brain abscess materials or immunocompetent patients.\textsuperscript{12} We identified this etiological agent in an immunocompetent patient with a left frontal intracerebral abscess that was treated successfully with craniotomy and drainage. In our series, a microbial agent was not identified in most cases. Staphylococci species were the most common microbial agents that caused intracranial infection, followed by streptococci species. Aspergillus was isolated in 2 immunocompromised patients due to malignancies (Fig. 4). We inserted amphotericin-B in the abscess cavity during surgery following removal of the infection material. This technique was previously reported in the literature with satisfactory clinical results.\textsuperscript{20}

Surgical options for the treatment of brain infections are well known and defined in the literature.\textsuperscript{3,7,10,15,17} Craniotomy is the gold standard for superficial, large, or multiloculated abscess or empyemas while stereotactic methods or endoscopic approaches are preferred for deep-seated or small infections.\textsuperscript{7,24,28} According to Moosa et al.,\textsuperscript{24} endoport-assisted surgical resection of deep-seated cerebral abscesses is feasible, safe, and effective in appropriately selected patients. The endoport system provides adequate visualization of deep abscesses, which allows extensive excision and drainage while minimizing parenchymal damage and white matter retraction. We used this technique in 2 cases in combination with the neuronavigation system, and the abscess material was evacuated using the endoscopic technique (Fig. 7). Although endoport-assisted resection provides easy abscess drainage, it is not enough to perform abscess wall perforation for the prevention of recurrence. Craniotomy plus microsurgery is more effective and safer for abscess wall perforation and drainage.
This method also provides clear exposure of the abscess environment for washing with antimicrobial agents.

Adequate drainage of the infection material (pus and capsule) leads to clinical improvement as well as neurologic and hemodynamic stability. The main aim of surgery is to drain the entire infection material and to decompress the brain in a single attempt, but this goal is seldom achieved with endoscopic or stereotactic methods. In the case of a dense or strong abscess wall, infection material can be left in situ, but abscess wall sampling is crucial for histopathological examination.

A subdural empyema can be misdiagnosed as a subdural hematoma or fluid collection. Contrast-enhanced radiological examinations are necessary for the differential diagnosis of subdural empyema (Fig. 2). In the case of a large amount of brain edema associated with fever and elevated white blood cells and sedimentation rate, radiological examinations should always be performed with contrast agents. Previous neurosurgical procedures, heart disease, and trauma should also be included in the patient’s medical history for an accurate diagnosis. Moreover, subdural empyemas are a causal factor in the pathogenesis of cerebral venous thrombosis in adults. Therefore, these lesions should be treated urgently in order to avoid cortical vein thrombosis or cerebral infarction. In our series, 34 of 52 patients had subdural empyema and underwent surgical treatment via craniotomy. All operations were performed on an emergency basis, and only 1 patient died after surgery. We did not observe any case of cerebral infarction secondary to subdural empyema in our series.

This study has several limitations: first is its retrospective nature, second is the low number of cases, and third is the lack of a sufficient follow-up period for a better clinical outcome.

Conclusions

Surgical treatment of intracranial infections requires good surgical skills, experience, and anatomical knowledge. Each case should be managed individually according to the patient’s clinical and radiological features. Complete drainage of the material should always be balanced with the anatomical location of the infection. Sampling and histological examination of the abscess wall is of paramount importance for an accurate diagnosis.
