The univariate piecing-together approach (PT) fits a univariate generalized Pareto distribution (GPD) to the upper tail of a given distribution function in a continuous manner. We propose a multivariate extension. First it is shown that an arbitrary copula is in the domain of attraction of a multivariate extreme value distribution if and only if its upper tail can be approximated by the upper tail of a multivariate GPD with uniform margins.

The multivariate PT then consists of two steps: The upper tail of a given copula \(C\) is cut off and substituted by a multivariate GPD copula in a continuous manner. The result is again a copula. The other step consists of the transformation of each margin of this new copula by a given univariate distribution function.

This provides, altogether, a multivariate distribution function with prescribed margins whose copula coincides in its central part with \(C\) and in its upper tail with a GPD copula.

When applied to data, this approach also enables the evaluation of a wide range of rational scenarios for the upper tail of the underlying distribution function in the multivariate case. We apply this approach to operational loss data in order to evaluate the range of operational risk.

Keywords: copula; domain of multivariate attraction; GPD copula; multivariate extreme value distribution; multivariate generalized Pareto distribution; operational loss; peaks over threshold; piecing together

1. Introduction

The peaks over threshold approach (POT) shows that the upper tail of a univariate distribution function \(F\) can reasonably be approximated only by that of a generalized Pareto distribution (GPD). This result goes back to Balkema and de Haan [2] and Pickands [30]. A univariate GPD \(W\) is derived from an extreme value distribution (EVD) \(G\) by the equality

\[
W(x) = 1 + \log(G(x)), \quad 1/e \leq G(x),
\]
where, with a shape parameter $\alpha > 0$, the family of standardized EVD is given by

\begin{align*}
G_{1,\alpha}(x) &= \exp(-x^{-\alpha}), \quad x > 0, \\
G_{2,\alpha}(x) &= \exp(-(-x)^\alpha), \quad x \leq 0, \\
G_3(x) &= \exp(-e^{-x}), \quad x \in \mathbb{R},
\end{align*}

being the Fréchet, (reverse) Weibull and Gumbel case of an EVD.

The family of univariate standardized GPD is, consequently, given by

\begin{align*}
W_{1,\alpha}(x) &= 1 - x^{-\alpha}, \quad x \geq 1, \\
W_{2,\alpha}(x) &= 1 - (-x)^\alpha, \quad -1 \leq x \leq 0, \\
W_3(x) &= 1 - \exp(-x), \quad x \geq 0,
\end{align*}

being the Pareto, beta and exponential case of a GPD.

If $X$ is a univariate random variable with distribution function $F$, then the distribution function $F[x_0]$ of $X$, conditional on the event $X > x_0$, is given by

\begin{align*}
F[x_0](x) &= P(X \leq x \mid X > x_0) \\
&= \frac{F(x) - F(x_0)}{1 - F(x_0)}, \quad x \geq x_0,
\end{align*}

where we require $F(x_0) < 1$. The POT approach shows that $F[x_0]$ can reasonably be approximated only by a GPD with appropriate shape, location and scale parameter $W_{\gamma,\mu,\sigma}$.

Note that

\begin{align*}
F(x) &= (1 - F(x_0))F[x_0](x) + F(x_0) \\
&\approx (1 - F(x_0))W_{\gamma,\mu,\sigma}(x) + F(x_0), \quad x \geq x_0.
\end{align*}

The piecing together approach (PT) now consists in replacing the distribution function $F$ by

\begin{align*}
F_{x_0}^*(x) &= \begin{cases} 
F(x), & x < x_0, \\
(1 - F(x_0))W_{\gamma,\mu,\sigma}(x) + F(x_0), & x \geq x_0,
\end{cases}
\end{align*}

where the shape, location and scale parameters $\gamma, \mu, \sigma$ of the GPD are typically estimated from given data. This modification aims at a more precise investigation of the upper end of the data.

Replacing $F$ in (2) by the empirical distribution function $\hat{F}_n$ of $n$ independent copies of $X$ offers in particular a semi-parametric approach to the estimation of high quantiles $F^{-1}(q) = \inf\{t \in \mathbb{R} : F(t) \geq q\}$ outside the range of given data; see, for example, Section 2.3 of Reiss and Thomas [33].

In this paper we propose an extension of the PT in (2) to higher dimensions. When applied to data, this approach also enables the evaluation of a wide range of rational
scenarios for the upper tail of the underlying distribution function in the multivariate case. This will be exemplified in Section 4 for operational loss data, where we simulate different scenarios for risk parameters such as the value at risk or the expected shortfall. In Section 2 we provide the basic mathematics for our PT approach. We will show that an arbitrary copula can reasonably be approximated in its upper tail only by a GPD with uniform margins.

The multivariate PT approach, which will be established in Section 3, now consists of two steps:

(i) The upper tail of a given $m$-dimensional copula $C$ is cut off and substituted by the upper tail of multivariate GPD copula in a continuous manner such that the result is again a copula.

(ii) The other step consists of the transformation of each margin of this new copula by a given univariate distribution function $F^*_i$, $1 \leq i \leq m$.

This provides, altogether, a multivariate distribution function with prescribed margins $F^*_i$, whose copula coincides in its central part with $C$ and in its upper tail with a GPD copula. In Section 4.2 we will simulate the effects that the combination of univariate and multivariate PT has on quantile functions and mean excess functions, or, in terms of risk analysis, on value at risk and expected shortfall. It turns out that in our specific model, which will be specified in Section 4, the application of the multivariate PT approach leads to a rising expected shortfall while the value at risk keeps (up to a level of 99.9%) nearly unchanged.

Instead of fitting a GPD to the upper tail of a distribution, estimation of rare events in the multivariate case can also be based on the fact that the exponent measure pertaining to a multivariate GPD is homogeneous; see de Haan and Sinha [11] and de Haan and Ronde [9] for details.

For recent accounts of basic and advanced topics of extreme value theory and statistics, see the monographs by Reiss and Thomas [33], de Haan and Ferreira [10] and Resnick [34].

2. Multivariate GPD

In this section we provide the mathematics underlying our PT approach, which will be established in Section 3.

Let $F$ be an arbitrary $m$-dimensional distribution function that is in the domain of attraction of an $m$-dimensional EVD $G$; that is, there exist norming constants $a_n > 0$, $b_n \in \mathbb{R}^m$ such that

$$F^n(a_n x + b_n) \xrightarrow{n \to \infty} G(x), \quad x \in \mathbb{R}^m, \quad (3)$$

where all operations on vectors are meant componentwise. The distribution function $G$ is max stable; that is, there exist norming constants $c_n > 0$, $d_n \in \mathbb{R}^m$ with

$$G^n(c_n x + d_n) = G(x), \quad x \in \mathbb{R}^m.$$ 

The one-dimensional margins $G_i$ of $G$ are up to scale and location parameters univariate EVD in (1).
It is well known that (3) is equivalent with convergence of the univariate margins together with convergence of the copulas
\[
\lim_{n \to \infty} C_F^n(u^{1/n}) = C_G(u) = G(G_1^{-1}(u_1), \ldots, G_m^{-1}(u_m)), \quad u \in (0, 1)^m,
\]
(Deheuvels [12, 13], Galambos [19]). For a recent account on copulas, see Nelsen [29]. Some elementary computations as in Falk [16], Section 6, or de Haan and Ronde [9], Section 4.2, entail that convergence (4) is equivalent with
\[
\lim_{t \downarrow 0} \frac{1}{t} (1 - C_F(1 + tx)) = l_G(x) := -\log(C_G(\exp(x))), \quad x \leq 0,
\]
where \(l_G\) is known as the stable tail dependence function introduced by Huang [22]. For a detailed discussion of the stable tail dependence function, see Beirlant et al. [3]. The stable tail dependence function is homogeneous \(tl_G(tx) = l_G(tx), t \geq 0,\) and, thus, (5) becomes
\[
\frac{1 - C_F(1 + tx) - l_G(tx)}{t} \to_{t \downarrow 0} 0.
\]
Observe that \(l_G(x) = 1 - H(x), x \leq 0,\) where \(H\) is a multivariate GP function with uniform margins \(H_i(x) = 1 + x, x \leq 0, i \leq m;\) that is,
\[
H(x) = 1 + \log(\tilde{G}(x)), \quad x \leq 0,
\]
and \(\tilde{G}\) is a multivariate EVD with negative exponential margins \(\tilde{G}_i(x) = \exp(x), x \leq 0, i \leq m.\)

We call in general an \(m\)-dimensional distribution function \(W\) a multivariate GPD if its upper tail coincides with a GP function; that is, there exist a multivariate EVD \(G\) and a vector \(x_0 \in \mathbb{R}^m\) with \(G(x_0) < 1\) such that
\[
W(x) = 1 + \log(G(x)), \quad x \geq x_0.
\]

Note that \(H(x) = 1 + \log(G(x)), G(\mathbf{x}) \geq 1/e,\) does not define a distribution function unless \(m \in \{1, 2\};\) see Michel [27], Theorem 6. We, therefore, call \(H\) a GP function. It is, actually, a quasi-copula (Alsina et al. [1], Genest et al. [20] and Section 5.1 in Falk et al. [17]). Lemma 5.1.5 in Falk et al. [17] implies, on the other hand, that for any GP function there exists a distribution function \(W\) satisfying (6).

The preceding considerations together with elementary computations entail now the following characterization of domains of attraction in terms of a GPD. By \(\| \cdot \|\) we denote an arbitrary norm on \(\mathbb{R}^m.\)

**Theorem 2.1.** An arbitrary distribution function \(F\) is in the domain of attraction of a multivariate EVD \(G\) if and only if this is true for the univariate margins and if there exists a GPD \(W\) with ultimately uniform margins \(W_i(x) = 1 + x, x_0 \leq x \leq 0, i \leq m,\) such that
\[
C_F(y) = W(y - 1) + o(\|y - 1\|)
\]
uniformly for \(y \in [0, 1]^m.\)
We have the following equivalences for an arbitrary copula \( C \) to lie in the domain of attraction of an EVD.

**Corollary 2.2.** \( C \) is in the domain of attraction of an EVD \( G \)

\[ \iff \text{There exists a GPD } W \text{ with ultimately uniform margins such that} \]
\[ C(y) = W(y-1) + o(\|y-1\|), \]

uniformly for \( y \in [0,1]^m \). In this case \( W(x) = 1 + \log(G(x)), \ x_0 \leq x \leq 0 \in \mathbb{R}^m \).

\[ \iff \text{There exists a norm } \| \cdot \|_D \text{ on } \mathbb{R}^m \text{ such that} \]
\[ C(y) = 1 - \|y-1\|_D + o(\|y-1\|_D), \]

uniformly for \( y \in [0,1]^m \). In this case \( G(x) = \exp(-\|x\|_D), \ x \leq 0 \).

Recall that all norms on \( \mathbb{R}^m \) are equivalent and, thus, \( o(\|y-1\|_D) \) in the second equivalence above can be substituted by \( o(\|y-1\|) \) with an arbitrary norm \( \| \cdot \| \) on \( \mathbb{R}^m \).

The preceding results show that the upper tail of the copula \( F \) of a distribution function \( F \) can reasonably be approximated only by that of a GPD \( W \) with ultimately uniform margins. To the best of our knowledge, this provides new insight into the significance of multivariate GPD. But it is in accordance with Rootzén and Tajvidi [35], who showed that, in the multivariate case, modelling exceedances of a random variable over a high threshold can rationally be done only by a multivariate GPD.

**Proof of Corollary 2.2.** It is well known that a GPD \( W \) with ultimately uniform margins can be written as

\[ W(x) = 1 - \|x\|_D, \quad x_0 \leq x \leq 0, \]

where \( \| \cdot \|_D \) is a norm on \( \mathbb{R}^m \) with particular properties, called a \( D \)-norm; see Section 4.4 in Falk et al. [17]. In particular, \( G(x) = \exp(-\|x\|_D), \ x \leq 0 \), defines an EVD on \( \mathbb{R}^m \). If \( C(y) = W(y-1) + o(\|y-1\|), \ y \in [0,1]^m \), for some norm \( \| \cdot \| \) on \( \mathbb{R}^m \), then

\[ C^n\left(1 + \frac{y}{n}\right) = \left(1 - \frac{1}{n}\|y\|_D + o\left(\frac{1}{n}\|y\|_D\right)\right)^n \]
\[ \to \exp(-\|y\|_D) = G(y), \quad y \leq 0. \]

Together with Theorem 2.1 this implies Corollary 2.2. □

In the final equivalence of Corollary 2.2, the norm can obviously be computed as

\[ \|x\|_D = \lim_{t \to 0} \frac{1 - C(1+tx)}{t} = \ell(x), \quad x \leq 0; \]

that is, it is the stable tail dependence function. It turns out that any stable tail dependence function is actually a norm. This explains why it is a convex function and homogeneous of order one.
Example 2.3. Take an arbitrary Archimedean copula

\[ C_\varphi(u) = \varphi^{-1}(\varphi(u_1) + \cdots + \varphi(u_m)), \]

where the generator \( \varphi : (0, \infty) \to [0, \infty) \) is a continuous function that is strictly decreasing on \((0, 1]\), \( \varphi(1) = 0 \), \( \lim_{x \downarrow 0} \varphi(x) = \infty \) and \( \varphi^{-1}(t) = \inf\{x > 0 : \varphi(x) \leq t\}, \ t \geq 0. \)

Note that \( C_\varphi \) is not automatically a copula for each function \( \varphi : (0, \infty) \to [0, \infty) \) as above. While, in the bivariate case \( m = 2 \), convexity of \( \varphi^{-1} \) is a necessary and sufficient condition, this is no longer true in higher dimension \( m \geq 3 \). Instead, \( C_\varphi \) is, for general dimension \( m \geq 2 \), a copula if and only if \( \varphi^{-1} \) is differentiable up to order \( m - 2 \), the derivatives satisfy \( (-1)^k(\varphi^{-1})^{(k)}(x) \geq 0, \ k = 0, \ldots, m - 2, \ x \in (0, \infty) \) and further if \( (-1)^{m-2}(\varphi^{-1})^{(m-2)} \) is non-increasing and convex in \((0, \infty)\); see McNeil and Neslehová [24], Theorem 2.2.

If \( \varphi \) is differentiable from the left in \( x = 1 \) with left derivative \( \varphi'(1-) \neq 0 \), then

\[ \lim_{t \downarrow 0} \frac{1 - C_\varphi(1 + tx)}{t} = \sum_{i \leq m} |x_i| = \|x\|_1, \quad x \leq 0; \]

that is, each Archimedean copula with a generator \( \varphi \) as above is in the domain of attraction of the EVD \( G(x) = \exp(-\|x\|_1), \ x \leq 0 \), with independent margins. The margins of \( C_\varphi \) are, therefore, tail independent; that is, the tail dependence parameters vanish:

\[ \chi(i, j) := \lim_{x \uparrow 1} P(U_i > x | U_j > x) = 0, \quad 1 \leq i \neq j \leq m, \]

where the random vector \((U_1, \ldots, U_m)\) follows the distribution function \( C_\varphi \). For a discussion of the tail dependence parameter and further literature, see Section 6.1 in Falk et al. [17].

The preceding considerations concern, for example, the Clayton and the Frank copula, which have generators \( \varphi_C(t) = \vartheta^{-1}(t^{-\vartheta} - 1) \) and \( \varphi_F(t) = -\log((\exp(-\vartheta t) - 1)/ (\exp(-\vartheta) - 1)), \ \vartheta > 0 \), but not the Gumbel copula with parameter \( \lambda > 1 \), which has generator \( \varphi_G(t) = -(\log(t))^\lambda, \lambda \geq 1, \ 0 < t \leq 1. \)

Any multivariate EVD \( G \) has univariate EVD margins and any multivariate GPD \( W \) has univariate GPD margins in its upper tail. We can transform an arbitrary multivariate EVD to an EVD with negative exponential margins by just transforming the margins. Equally, we can transform an arbitrary \( W \) to a GPD with uniform margins by just transforming the margins. This transformation can also be done backwards; see Section 5.6 in Falk et al. [17]. We will, therefore, consider in what follows multivariate GPD derived from an EVD \( G \) with negative exponential margins. For a recent account on multivariate GPD, see Michel [25].

From the de Haan–Resnick–Pickands representation of a multivariate EVD, it is well known that a function \( G \) on \((-\infty, 0]^m \) is the distribution function of an EVD with negative standard exponential margins \( G_i(x) = \exp(x), \ x \leq 0, \ i \leq m, \) if and only if it can be represented as

\[ G(x) = \exp\left(\int_{\mathbb{R}^m} \min(x; t) \mu(dt)\right), \quad x \leq 0, \]
where \( \mu \) is a finite measure on \( S_m := \{ t \geq 0 : \sum_{i \leq m} t_i = 1 \} \), called an angular measure, with the characteristic property \( \int_{S_m} t_i \mu(\mathrm{d}t) = 1, \ i \leq m; \) see Section 4.2 in Falk et al. [17]. Note that this integrability condition on \( \mu \) implies that \( \mu(S_m) = \int_{S_m} 1 \, \mathrm{d}\mu = \int_{S_m} \sum_{i \leq m} t_i \mu(\mathrm{d}t) = \sum_{i \leq m} \int_{S_m} t_i \mu(\mathrm{d}t) = m. \)

As a consequence we obtain that a multivariate GPD \( W \) with standard uniform margins \( 1 - W_i(x) = x, \ i \leq m, \) in a left neighborhood of \( \mathbf{0} \in \mathbb{R}^m \) can be represented as

\[
W(\mathbf{x}) = 1 + \left( \sum_{j \leq m} x_j \right) \int_{S_m} \max(\bar{x}, t_i) \mu(\mathrm{d}t)
=: 1 + \left( \sum_{j \leq m} x_j \right) D(\bar{x}_1, \ldots, \bar{x}_{m-1})
\]

(7)

for \( \mathbf{x}_0 \leq \mathbf{x} \leq \mathbf{0} \), where \( \mu \) is as above, \( \bar{x}_i = x_i / \sum_{j \leq m} x_j \) and \( D: \{ \mathbf{u} \in [0, 1]^{m-1} : \sum_{j \leq m-1} u_j \leq 1 \} \to [1/m, 1] \) is a Pickands dependence function (Section 4.3 in Falk et al. [17]).

The following result characterizes a GPD with uniform margins in terms of random variables. It provides an easy way to generate a multivariate GPD, thus extending the bivariate approach proposed by Buishand et al. [6] to an arbitrary dimension. Recall that an arbitrary multivariate GPD can be obtained from a GPD with ultimately uniform margins by just transforming the margins. For a recent account on simulation techniques of multivariate GPD, see Michel [26].

**Proposition 2.4.**

(i) Let \( W \) be a multivariate GPD with standard uniform margins in a left neighborhood of \( \mathbf{0} \in \mathbb{R}^m \). Then there is a random vector \( \mathbf{Z} = (Z_1, \ldots, Z_m) \) with \( Z_i \in [0, m] \) and \( E(Z_i) = 1, \ i \leq m, \) and a vector \((-1/m, \ldots, -1/m) \leq \mathbf{x}_0 < \mathbf{0} \) such that

\[
W(\mathbf{x}) = P\left(-U \left( \frac{1}{Z_1}, \ldots, \frac{1}{Z_m} \right) \leq \mathbf{x} \right), \quad \mathbf{x}_0 \leq \mathbf{x} \leq \mathbf{0},
\]

where the random variable \( U \) is uniformly distributed on \((0,1)\) and independent of \( \mathbf{Z} \).

(ii) The random vector \(-U(1/Z_1, \ldots, 1/Z_m)\) follows a GPD with standard uniform margins in a left neighborhood of \( \mathbf{0} \in \mathbb{R}^m \) if \( U \) is independent of \( \mathbf{Z} = (Z_1, \ldots, Z_m) \) and \( 0 \leq Z_i \leq c_i \) a.s. with \( E(Z_i) = 1, \ i \leq m, \) for some \( c_1, \ldots, c_m \geq 1 \).

Note that the case of a GPD \( W \) with arbitrary uniform margins \( W_i(x) = 1 - a_i x \) in a left neighborhood of \( \mathbf{0} \) with arbitrary scaling factors \( a_i > 0, \ i \leq m \), immediately follows from the preceding result by substituting \( Z_i \) by \( a_i Z_i \).

**Proof of Proposition 2.4.** First we establish part (i). From representation (7) we obtain that for \( \mathbf{x} \) in a left neighborhood of \( \mathbf{0} \in \mathbb{R}^m \)

\[
W(\mathbf{x}) = 1 + \left( \sum_{j \leq m} x_j \right) \int_{S_m} \max(\bar{x}, t_i) \mu(\mathrm{d}t)
\]

with some measure \( \mu \) on \( S_m \) such that \( \mu(S_m) = m \) and \( \int_{S_m} t_i \mu(\mathrm{d}t) = 1, \ i \leq m. \)
Now \( \tilde{\mu}() = \mu() / m \) defines a probability measure on \( S_m \). Let \( T = (T_1, \ldots, T_m) \) be a random vector with values in \( S_m \) that has distribution \( \tilde{\mu} \) and put \( Z := mT \). Then \( Z \in [0, m]^m \) and \( E(Z_i) = \int_{S_m} t_i \mu(\text{d}t) = 1, \ i \leq m \). We have, further, for \( x \leq 0 \in \mathbb{R}^m \) with \( x_j \geq -1/m, \ j \leq m \),

\[
P\left(-U\left(\frac{1}{Z_1}, \ldots, \frac{1}{Z_m}\right) \leq x\right) = P\left(-U\left(\frac{1}{T_1}, \ldots, \frac{1}{T_m}\right) \leq mx\right)
\]

\[
= \frac{1}{m} \int_{S_m} P\left(-U\left(\frac{1}{T_1}, \ldots, \frac{1}{T_m}\right) \leq mx \mid T = t\right)(P \ast T)(\text{d}t)
\]

\[
= \frac{1}{m} \int_{S_m} P\left(-U\left(\frac{1}{T_1}, \ldots, \frac{1}{T_m}\right) \leq mx\right)\tilde{\mu}(\text{d}t)
\]

\[
= \frac{1}{m} \int_{S_m} P\left(U \geq m \max_{i \leq m}(-x_i t_i)\right)\mu(\text{d}t)
\]

\[
= \frac{1}{m} \int_{S_m} P\left(U \geq -m \sum_{j \leq m} x_j \max_{i \leq m}(\tilde{x}_i t_i)\right)\mu(\text{d}t)
\]

\[
= \frac{1}{m} \int_{S_m} 1 + m \left(\sum_{j \leq m} x_j \max_{i \leq m}(\tilde{x}_i t_i)\right)\mu(\text{d}t)
\]

\[
= 1 + \left(\sum_{j \leq m} x_j\right)\int_{S_m} \max_{i \leq m}(\tilde{x}_i t_i)\mu(\text{d}t).
\]

This implies part (i) of the proposition.

On the other hand, we have for \( x \leq 0 \) and large \( s > 0 \)

\[
P\left(-U\left(\frac{1}{Z_1}, \ldots, \frac{1}{Z_m}\right) \leq \frac{1}{s}x\right) ^ s
\]

\[
= \left(\int_{[0, e]} P\left(U \geq \frac{1}{s} \max_{i \leq m}(-x_i z_i)\right)(P \ast Z)(\text{d}z)\right) ^ s
\]

\[
= \left(1 - \frac{1}{s} \int_{[0, e]} \max_{i \leq m}(-x_i z_i)(P \ast Z)(\text{d}z)\right) ^ s
\]

\[
to \exp\left(- \int_{[0, e]} \max_{i \leq m}(-x_i z_i)(P \ast Z)(\text{d}z)\right) =: G(x)
\]

with \( c = (c_1, \ldots, c_m) \).
Lemma 7.2.1 in Reiss [32] now implies that $G$ is a distribution function that is obviously max stable: $G^*(s^{-1}x) = G(x), s > 0$; that is, $G$ is a multivariate EVD and has negative standard exponential margins $G_i(x) = \exp(xE(Z_i)) = \exp(x), x \leq 0$. As a consequence, $1 + \log(G(x))$ is a GP function with

$$1 + \log(G(x)) = 1 - \int_{[0,1]} \max(-x_i z_i)(P * Z)(dz)
= P\left(-U\left(\frac{1}{Z_1}, \ldots, \frac{1}{Z_m}\right) \leq x\right)$$

for $x_0 \leq x \leq 0$ and some $x_0 < 0$. □

Let, for instance, $C$ be an arbitrary $m$-dimensional copula; that is, $C$ is the distribution function of a random vector $S$ with uniform margins $P(S_i \leq s) = s, s \in (0,1), i \leq m,$ (Nelsen [29]). Then $Z := 2S$ is a proper choice in part (ii) of Proposition 2.4. Proposition 2.4, therefore, maps the set of copulas in a natural way to the set of multivariate GPDs, thus opening a wide range of possible scenarios.

According to Theorem 2.1, we call a copula $C_W$ a GPD copula on $[0,1]^m$ or simply a GPD copula if there exists $y_0 < 1$ such that

$$C_W(y) = W(y - 1), \quad y_0 \leq y \leq 1,$$

where $W$ is a GPD with standard uniform margins in a left neighborhood of zero.

For mathematical convenience we temporarily shift a copula to the interval $[-1,0]^m$ by shifting each univariate margin by $-1$. Thus we obtain a distribution function $\tilde{C}_W$ from a GPD copula $C_W$, whose marginal distribution functions are the uniform distribution on $[-1,0]$, and $\tilde{C}_W$ coincides close to zero with a GPD $W$ as in equation (7); that is, there exists $x_0 < 0$ such that

$$\tilde{C}_W(x) = W(x_1, \ldots, x_m)
= 1 + \left(\sum_{j \leq m} x_j\right) \int_{S_m} \max_{i \leq m} t_i \left(\sum_{j \leq m} x_j\right) \mu(dt), \quad x \in [x_0, 0].$$

Because $\tilde{C}_W$ inherits its properties from the original GPD copula $C_W$, we call $\tilde{C}_W$ a GPD copula on $[-1,0]^m$.

For later purposes we remark that a random vector $V \in [-1,0]^m$ following a GPD copula on $[-1,0]^m$ can easily be generated as follows, using Proposition 2.4. Let $U$ be uniformly distributed on $(0,1)$ and independent of the vector $S = (S_1, \ldots, S_m)$, which follows an arbitrary copula on $[0,1]^m$. Then we have for $i \leq m$

$$P\left(-U\frac{1}{2S_i} \leq x\right) = \begin{cases} 1 + x, & \text{if } -\frac{1}{2} \leq x \leq 0, \\ \frac{1}{4|x|}, & \text{if } x < -\frac{1}{2}, \end{cases}
=: H(x), \quad x \leq 0,$$
and, consequently,
\[ V := \left( H\left( -\frac{U}{2S_1} \right) - 1, \ldots, H\left( -\frac{U}{2S_m} \right) - 1 \right) = (V_1, \ldots, V_m) \]

with
\[ V_i = \begin{cases} -\frac{U}{2S_i}, & \text{if } U \leq S_i, \\ \frac{S_i}{2U} - 1, & \text{if } U > S_i, \end{cases} \quad (8) \]

follows by Proposition 2.4 a GPD copula on \([-1,0]^m\).

3. Multivariate piecing together

The multivariate PT approach consists of two steps. In a first step, the upper tail of a given \(m\)-dimensional copula \(C\) is cut off and substituted by the upper tail of multivariate GPD copula in a continuous manner. The result is again a copula, that is, an \(m\)-dimensional distribution with uniform margins. The other step consists of the transformation of each margin of this copula by a given univariate distribution function \(F_i\), \(1 \leq i \leq m\). This provides, altogether, a multivariate distribution function with prescribed margins \(F_i\) whose copula coincides in its central part with \(C\) and in its upper tail with a GPD copula.

We start with fitting a GPD copula to the upper tail of a given copula \(C\) on \([-1,0]^m\). Recall that for mathematical convenience we shift any copula \(\tilde{C}(u), u \in [0,1]^m\), to a copula on \([-1,0]^m\) by setting \(C(v) = \tilde{C}(1 + v), v \in [-1,0]^m\).

Let \(V = (V_1, \ldots, V_m)\) follow a GPD copula on \([-1,0]^m\); that is, \(P(V_i \leq x) = 1 + x, -1 \leq x \leq 0\) is for each \(i \leq m\) the uniform distribution on \([-1,0]\), and there exists \(x_0 = (x_0^{(1)}, \ldots, x_0^{(m)}) < 0\) such that for each \(x = (x_1, \ldots, x_m) \in [x_0, 0]\)

\[ P(V \leq x) = 1 + \left( \sum_{i \leq m} x_i \right) D\left( \frac{x_1}{\sum_{i \leq m} x_i}, \ldots, \frac{x_{m-1}}{\sum_{i \leq m} x_i} \right), \]

where \(D\) is a Pickands dependence function.

Let \(Y = (Y_1, \ldots, Y_m)\) follow an arbitrary copula \(C\) on \([-1,0]^m\) and suppose that \(Y\) is independent of \(V\). Choose a threshold \(y = (y_1, \ldots, y_m) \in [-1,0]^m\) and put

\[ Q_i := Y_i 1_{(Y_i \leq y_i)} - y_i V_i 1_{(Y_i > y_i)}, \quad i \leq m. \]  (9)

The random vector \(Q\) then follows a GPD copula on \([-1,0]^m\), which coincides with \(C\) on \(\times_{i \leq m} [-1, y_i]\). This is the content of the main result of this section.

**Proposition 3.1.** Suppose that \(P(Y > y) > 0\). Each \(Q_i\) defined in (9) follows the uniform distribution on \([-1,0]\). The random vector \(Q = (Q_1, \ldots, Q_m)\) follows a GPD copula.
on $[-1,0]^m$, which coincides with $C$ on $\times_{i \leq m} [-1, y_i]$; that is,

$$P(Q \leq x) = C(x), \quad x \leq y.$$

We have, moreover, with $x_i \in [\max(y_i, x_0^{(i)}), 0]$, $i \leq m$, for any non-empty subset $K$ of $\{1, \ldots, m\}$

$$P(Q_i \geq x_i, i \in K) = P(V_i \geq b_i, i \in K),$$

where

$$b_i := \frac{P(Y_j > y_j, j \in K)}{-y_i} = \frac{P(Y_j > y_j, j \in K)}{P(Y_i > y_i)} \in (0,1], \quad i \in K.$$

**Proof.** First we show that each $Q_i$ follows the uniform distribution on $[-1,0]$. We have for $-1 \leq x \leq y$

$$P(Q_i \leq x) = P(Q_i \leq x, Y_i \leq y_i) + P(Q_i \leq x, Y_i > y_i)$$

$$= P(Y_i \leq x)$$

$$= 1 + x,$$

whereas for $y_i < x \leq 0$ we obtain

$$P(Q_i \leq x) = P(Y_i \leq y_i) + P(-y_i, Y_i \leq x) P(Y_i > y_i)$$

$$= 1 + y_i + P(V_i \leq -\frac{x}{y_i})(-y_i)$$

$$= 1 + y_i + \left(1 - \frac{x}{y_i}\right)(-y_i)$$

$$= 1 + x.$$ 

The random vector $Q$, thus, follows a copula on $[-1,0]^m$. We have, further, for $x \leq y$

$$P(Q \leq x) = P(Q \leq x, Y \leq y) + P(Q \leq x, Y \notin y)$$

$$= P(Y \leq x)$$

$$= C(x).$$

By Proposition 2.1 in Falk and Michel [18] we have with $x_i \in [\max(y_i, \omega_i), 0]$, $i \leq m$, $t \in [0,1]$ and an arbitrary subset $K \subset \{1, \ldots, m\}$

$$P(Q_j > tx_j, j \in K) = P(Q_j > tx_j, Y_j > y_j, j \in K)$$

$$= P(-y_j V_j > tx_j, j \in K) P(Y_j > y_j, j \in K)$$

$$= t P(-y_j V_j > x_j, j \in K) P(Y_j > y_j, j \in K)$$

$$= t P(Q_j > x_j, j \in K),$$

which, again by Proposition 2.1 in Falk and Michel [18], implies that $Q$ follows a GPD.
We have, moreover, with \( x_i \in \max(y_i, \alpha_i), i \leq m, \)
\[
P(Q_i \geq x_i, i \in K) = P(Q_i \geq x_i, Y_i > y_i, i \in K) + P(Q_i \geq x_i, Y_j \leq y_j \text{ for some } j \in K)
\]
\[
= P(-y_i V_i \geq x_i, i \in K) P(Y_i > y_i, i \in K)
\]
\[
= P \left( V_i \geq -\frac{x_i}{y_i}, i \in K \right) P(Y_i > y_i, i \in K)
\]
\[
= P(V_i \geq b_i, i \in K). \]

The above approach provides an easy way to generate a random vector \( X \in \mathbb{R}^m \) with
prescribed margins \( F_i^*, i \leq m, \) such that \( X \) has a given copula in the central part of the data, whereas in the upper tail it has a GPD copula.

Take \( Q = (Q_1, \ldots, Q_m) \) as in (9) and put \( \tilde{Q} : = (Q_1 + 1, \ldots, Q_m + 1) \). Then each component \( \tilde{Q}_i \) of \( \tilde{Q} \) is uniformly distributed on \( (0,1) \) and thus
\[
X : = (X_1, \ldots, X_m) : = (F_1^{-1}(\tilde{Q}_1), \ldots, F_m^{-1}(\tilde{Q}_m)) \tag{10}
\]
has the desired properties.

Combining the univariate and the multivariate PT approach now consists in choosing a threshold \( u(i) \in \mathbb{R} \) for each dimension \( i \leq m \) and a univariate distribution function \( F_i \) together with an arbitrary univariate GPD \( W_{\gamma_i, \mu_i, \sigma_i} \), and putting for \( i \leq m \)
\[
F_i^*(x) : = \begin{cases} 
F_i(x), & \text{if } x \leq u(i) \\
(1 - F_i(u(i)))W_{\gamma_i, \mu_i, \sigma_i}(x) + F_i(u(i)), & \text{if } x > u(i).
\end{cases} \tag{11}
\]

This is typically done in a way such that \( F_i^* \) is a continuous function.

4. An application to operational loss data

In this section we apply our multivariate PT approach to operational loss data. For an excellent introduction to operational risk and insurance analytics, see Chapter 10 of McNeil et al. [23] and the literature cited there. In the sequel we give a brief summary.

According to the New Basel Capital Accord (Basel II), banks are required to determine the regulatory capital charge for operational risk, defined as the risk of losses resulting from inadequate or failed internal processes, people and systems or from external events. The Basel Committee on Banking Supervision encourages the use and further development of advanced modelling techniques to quantify operational risk. The most risk-sensitive methodology is the loss distribution approach using bank internal data to estimate probability distribution functions for each business line/event type category.

To provide a greater consistency of loss data collection within and between banks, operational losses are classified in eight business lines and seven event types. To calculate the capital charge for each business line/event type combination, a risk measure such
as value at risk to the 99.9% confidence level over a one-year holding period is chosen. A conservative way to assess a bank’s total capital requirement is to sum up the capital charges across business line/event type classes assuming perfect dependence and disregarding diversification effects in operational risk. Actually, the fact that all severe losses occur in the same year is rather dubious. Therefore, the dependence structure among losses of different business line/event type categories needs to be modelled explicitly. For simplicity, we consider in what follows only business lines and not event types.

The frequency of a loss event for business line $i$ over a one-year time horizon will be denoted by $N(i)$. The random loss associated with the $k$th loss event for business line $i$ will be denoted by $\zeta_k(i)$.

The random loss $L(i)$ over one year for business line $i$ is, therefore, modelled as

$$L(i) = \sum_{k=1}^{N(i)} \zeta_k(i),$$

where $\zeta_1(i), \zeta_2(i), \ldots$ are assumed to be i.i.d. with distribution function $F_i$ and they are independent of their total number $N(i)$.

The goal is to model the total loss distribution for operational risk; that is, the distribution of

$$L := \sum_{i=1}^{m} L(i),$$

or parameters of it such as the value at risk $\text{VAR}(\alpha)$ at the probability level $\alpha$ satisfying

$$P(L \geq \text{VAR}(\alpha)) = 1 - \alpha$$

or the expected shortfall at the probability level $\alpha$

$$\text{ES}(\alpha) := E(L \mid L \geq \text{VAR}(\alpha)).$$

In order to assess the total capital charge, the traditional models for measuring operational risk determine $\text{VAR}(\alpha)$ and $\text{ES}(\alpha)$ for each of the $m$ business lines separately and then simply sum up the corresponding capital charges.

In contrast, Di Clemente and Romano [14] suggest modelling the dependence structure among $L(1), \ldots, L(m)$ by a copula function, precisely, by the copula corresponding to the $m$-dimensional t-distribution with $\nu$ degrees of freedom. For a closer look at the issue of modelling the dependence among components of a random vector of financial risk factors using the concept of a copula, see Chapter 5 of McNeil et al. [23].

In our application we analyse operational losses of the external database $\text{SAS OpRisk Global Data}$, which contains worldwide information on publicly reported operational losses over US $100\,000. Since we do not know the probability of losses lying under US $100\,000$, we neglect this cut-off limit in modelling the severity and frequency of the data. We concentrate on two business lines of the financial sector, $\text{Commercial banking}$ and $\text{Retail banking}$. 
First we follow the copula extreme value theory approach for modelling operational loss data as outlined in Di Clemente and Romano [14], but we add the multivariate PT approach developed in Section 3.

4.1. Estimation

Before applying the multivariate PT approach, we explore the characteristics of the empirical distributions of the two business lines and estimate the model’s parameters. Thereby the severity distribution of the random variable $\zeta_k(i)$ and the frequency distribution of the random variable $N(i)$, $i = 1, 2$, are treated separately. To obtain the distribution function of the total loss $L(i)$ of the business line $i$ over a one-year time horizon we accomplish a Monte Carlo simulation combining the severity distribution with the frequency distribution.

First we analyse the empirical distributions of the loss severity. The measures skewness and kurtosis indicate that the empirical distributions of the two business lines are skewed to the right and very heavy tailed.

In the next step, parametric distributions (i.e., Weibull, gamma and lognormal distribution) are fitted to the data. The parameters are estimated by the maximum likelihood method. With the help of graphical analysis (QQ plots, theoretical versus empirical distribution function plots) and goodness-of-fit tests (Anderson–Darling test, Cramer–von Mises (CvM) test), we conclude, that none of the selected distributions provides a good fit to the complete data sets. (For a detailed presentation and discussion of goodness-of-fit techniques, see D’Agostino and Stephens [8].) However, the lognormal distribution fits the body of the data very well, while it underestimates the severity of the data in the right tail.

Therefore, to fit the tail data accurately, the univariate POT method in the model of the severity distribution of the losses $\zeta_k(i)$ is applied: The existence of a threshold $u(i)$ for each business line $i$ is assumed such that $\zeta_k(i)$ follows a lognormal distribution function below $u(i)$, whereas above $u(i)$ it follows a univariate GPD, that is,

$$P(\zeta_k(i) \leq x) = \begin{cases} F_i(x), & x \leq u(i), \\ F_i(u(i)) + (1 - F_i(u(i))) \text{GPD}_{\beta(i), \xi(i)}(x - u(i)), & x \geq u(i), \end{cases}$$

(12)

where the GPD is given by

$$\text{GPD}_{\beta(i), \xi(i)}(z) := 1 - \left(1 + \xi(i) \frac{z}{\beta(i)}\right)^{-1/\xi(i)}, \quad z \geq 0,$$

with shape and scale parameter $\xi(i) > 0$, $\beta(i) > 0$. Furthermore, $F_i$ is defined as $F_i(x) := \Phi((\log(x) - \mu(i))/\sigma(i))$, where $\Phi$ is the standard normal distribution function and $\mu(i) \in \mathbb{R}$, $\sigma(i) > 0$ are location and scale parameters of the lognormal distribution.

In this case we obtain for $x \geq u(i)$

$$P(\zeta_k(i) > x) = P(\zeta_k(i) > u(i)) \left(1 + \xi(i) \frac{x - u(i)}{\beta(i)}\right)^{-1/\xi(i)}.$$
The threshold \( u(i) \) is chosen with the help of mean excess plots. The shape and scale parameters of the GPD are estimated by the maximum likelihood method. For a discussion of the parameter estimation of a GPD and optimal choice of the threshold, see Section 6 of Embrechts et al. [15].

To determine the frequency distribution of the random variable \( N(i) \), the Poisson and negative binomial distribution are fitted to the total number of losses per year. The parameters of these distributions are estimated by the method of moments. Since the negative binomial distribution has two parameters, \( \alpha \) and \( r \), it is more flexible and often provides a better fit to operational loss data than the Poisson distribution; see Cruz [7], page 89. With the help of the \( \chi^2 \) goodness-of-fit test, this expectation is confirmed. Therefore, the random variable \( N(i) \) is modelled by the negative binomial distribution, whose probability mass function is expressed as

\[
P(N(i) = n) = \binom{\alpha(i) + n - 1}{n} \left( \frac{1}{1 + r(i)} \right)^{\alpha(i)} \left( \frac{r(i)}{1 + r(i)} \right)^n, \quad n \in \mathbb{N}_0,
\]

with \( \alpha(i) > 0, r(i) > 0 \). The resulting estimates of the model’s parameters are given in Table 1.

In the following, we model the dependence structure among \( L(1) \) and \( L(2) \) by a copula function. The assumption of a normal copula has been quite popular in finance for modelling the dependence between different risks, but it puts less weight on observations that are large in each component; see, for example, Rachev et al. [31]. The \( t \) copula is more heavily tailed and, therefore, better suited for modelling operational risk.

In our bivariate case the \( t \) copula is fitted to the total loss data over a one-year time horizon. The parameter of the correlation matrix and the degrees of freedom \( \nu \) are estimated by the maximum likelihood method. For a discussion of the problem of fitting copulas to data, see Section 5.5 of McNeil et al. [23].

Table 2 contains the estimated correlation matrix for the \( t \) copula with \( \nu = 8.64 \) estimated degrees of freedom.

**Table 1. Estimated model parameters**

|              | \( \alpha(i) \) | \( r(i) \) | \( \mu(i) \) | \( \sigma(i) \) | \( u(i) \) | \( \beta(i) \) | \( \xi(i) \) |
|--------------|-----------------|------------|-------------|----------------|------------|-------------|------------|
| Commercial   | 0.74            | 46.10      | 2.19        | 2.23           | 918.02     | 609.84      | 0.82       |
| Retail       | 0.39            | 162.04     | 0.88        | 2.06           | 69.18      | 99.75       | 1.02       |

**Table 2. Estimated correlation matrix for the \( t \) copula**

|        | Commercial | Retail |
|--------|------------|--------|
| Commercial | 1         | 0.76   |
| Retail    | 0.76       | 1      |
Table 3. Goodness-of-fit test for the $t$ copula

| CvM statistic | $p$-value |
|---------------|-----------|
| 0.02543851    | 0.521978  |

To evaluate the goodness of fit of the $t$ copula, the CvM test is applied. For recent reviews of copula goodness-of-fit testing, see Berg [4] and Genest et al. [21]. In Table 3 the CvM test value and corresponding $p$-value are reported.

Since the $p$-value is 0.521978, the null hypothesis that the dependence structure of the data follows a $t$ copula is not rejected.

4.2. Simulation

In the previous section we estimated the parameters that specify a situation where only the univariate PT approach is applied. This model is similar to the one described in Di Clemente and Romano [14]. Now we show by simulations how popular risk measures such as value at risk or expected shortfall can be influenced by the combination of univariate and multivariate piecing together.

First we take the $t$ copula derived in Section 4.1 and add the multivariate PT approach developed in Section 3. We simulate $10^4$ independent copies of $\tilde{Y} = (\tilde{Y}_1, \tilde{Y}_2)$ and $V = (V_1, V_2)$, which follow the $t$ copula from above and a GPD copula on $[-1,0]^2$, respectively. The realizations of $Y := \tilde{Y} - 1$ and $V$ are then combined with those of a random vector $Q$ according to definition (9). The distribution of $Q$ is then a GPD copula on $[-1,0]^2$ which coincides with the previously mentioned $t$ copula – shifted by minus one – below some threshold vector $y = (y_1, y_2)$. The last step consists in shifting the realizations of $Q$ to the interval $[0,1]^2$ and transforming the margins by $F_1^*, F_2^*$ according to equation (10). ($F_1^*, F_2^*$ are derived from Monte Carlo simulations as described in Section 4.1.) Thus we obtain $10^4$ realizations of a random vector $X$ that follows a multivariate distribution function that has the marginal distribution functions $F_1^*, F_2^*$ and the associated copula is a GPD copula that coincides with the original $t$ copula in its central part. These realizations of $X$ are then taken to compute the empirical counterparts of the value at risk and the expected shortfall.

Before we apply these steps, we remark that there are still two remaining degrees of freedom in our model: the GPD copula that underlies $V$ and the copula threshold vector $y$. Our goal in this section is to give a first insight into the consequences of replacing the upper tail of a given copula with a GPD copula. (Note that this procedure is justified by Theorem 2.1 and Corollary 2.2.) For this purpose, we assume a simple model:

(i) We define the GPD copula underlying $V$ indirectly by setting $Z := 2S$ in Proposition 2.4, where $S$ follows a bivariate normal copula.

(ii) The copula threshold vector is obtained by $y := (F_1(u(1)), F_2(u(2))) - 1$; that is, the thresholds for the marginal distributions in the univariate PT approach (see equation (12)) are transformed and used for the multivariate PT approach, too.
This way, we construct a parametric model that is only dependent on the correlation matrix

\[ \Sigma = \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}, \quad \rho \in [0, 1), \]

of the random vector \( \mathbf{S} \). It is typically very difficult, particularly in higher dimensions, to find a good multivariate model that describes both marginal behavior and dependence structure effectively. The advantage of the preceding copula model is that it depends on just one parameter \( \rho \in [0, 1) \), allowing dependence and independence of the margins in a simple and continuous manner. We refer again to McNeil et al. [23].

The simulations as described above were now done for various values of \( \rho \). To attain more reliable estimates for the value at risk and the expected shortfall, we simulated not only once but 50 times and took the average. Additionally, these values were also computed for the case in which only the univariate PT approach is applied and the \( t \) copula kept unchanged. This procedure allows us to identify the effect the multivariate PT approach has on the mentioned risk measures.

In the following we state our results from the simulation series with \( \rho = 0.7 \), which models the case of relative high dependence but not complete dependence between the business lines. Although a graphical analysis of the used GPD copulas suggested that the degree of dependence in the upper tail was increasing with \( \rho \) getting larger, there was no observable trend in the estimates of the value at risk and the expected shortfall. Further research is necessary to derive criteria for the optimal choice of \( \rho \) or, more generally, of the GPD copula underlying \( \mathbf{V} \) and the copula threshold \( y \).

We now start with the presentation of the results. For simplicity, we identify the business lines Commercial banking and Retail banking with the cases \( i = 1 \) and \( i = 2 \), respectively. The random vector \( \mathbf{X} \) from above models the combined random losses for these two business lines over one year, that is, \( \mathbf{X} = (L(1), L(2)) \). The value at risk and the expected shortfall of \( L(1) \), \( L(2) \) and \( L = L(1) + L(2) \) were computed using their empirical counterparts

\[ \widehat{\text{VAR}}(\alpha) = \widehat{F}(1 - \alpha), \]

where \( \widehat{F} \) is the empirical distribution function of \( L(1) \), \( L(2) \) or \( L \), respectively, and

\[ \widehat{\text{ES}}(\alpha) = \frac{1}{n(1 - \alpha)} \sum_{i=1}^{n} l_i (1_{(\widehat{\text{VAR}}(\alpha), \infty)}(l_i)), \]

where \( l_i \) is the \( i \)th realization of \( L(1) \), \( L(2) \) or \( L \), respectively. By \( 1_B \) we denote the indicator function of a set \( B \), that is, \( 1_B(x) = 1 \) if \( x \in B \) and \( 1_B(x) = 0 \) otherwise.

Table 4 gives the means of 50 independent simulations resulting from the multivariate PT approach, whereas Table 5 makes use of the univariate approach only. Since the marginal distributions are the same in both cases, namely \( F_1^*, F_2^* \), the value at risk estimates concerning \( L(1), L(2) \) nearly coincide across both tables. It is apparent that the respective values for \( L \), the total loss, are only slightly different.

On the other hand, the empirical expected shortfalls attain clearly higher values if the upper tail of the \( t \) copula is substituted by a GPD. This behavior is independent of the \( \alpha \).
Table 4. Estimated value at risk and expected shortfall, GPD copula

|     | \(\hat{\text{VAR}}(\alpha)\) | \(\hat{\text{ES}}(\alpha)\) |
|-----|-----------------|-----------------|
|     | 95%  | 99%  | 99.5% | 99.9% | 95%  | 99%  | 99.5% | 99.9% |
| \(L(1)\) | 13 638 | 32 899 | 49 650 | 159 442 | 46 436 | 154 758 | 27 036 | 103 8077 |
| \(L(2)\) | 12 586 | 45 370 | 84 386 | 390 127 | 93 365 | 381 142 | 70 235 | 288 672 |
| \(L\) | 26 578 | 75 518 | 127 042 | 533 701 | 135 581 | 512 781 | 93 047 | 374 889 |

Table 5. Estimated value at risk and expected shortfall, \(t\) copula

|     | \(\hat{\text{VAR}}(\alpha)\) | \(\hat{\text{ES}}(\alpha)\) |
|-----|-----------------|-----------------|
|     | 95%  | 99%  | 99.5% | 99.9% | 95%  | 99%  | 99.5% | 99.9% |
| \(L(1)\) | 13 638 | 32 667 | 49 196 | 153 322 | 37 674 | 111 075 | 182 956 | 608 755 |
| \(L(2)\) | 12 590 | 45 601 | 83 414 | 392 673 | 71 288 | 270 821 | 482 058 | 177 423 |
| \(L\) | 25 428 | 75 674 | 131 267 | 533 710 | 105 122 | 366 904 | 637 184 | 226 144 |

level and holds for the losses in the single business lines as well as for the total loss in our simulation. This is remarkable since the corresponding estimates for the value at risk are in both cases nearly the same, indicating that there are some extreme high losses that occur very rarely.

Clearly, with underlying estimated GPD shape parameters \(\xi(1) = 0.82\) and \(\xi(2) = 1.02\), the theoretical expected shortfall exists only for \(i = 1\) but not for \(i = 2\). The significant increases for \(\hat{\text{ES}}(\alpha)\) in line \(L(1)\) and \(L(2)\) in Table 4 should, therefore, only be due to the high volatility of the empirical expected shortfall, whereas the significant increase in line \(L\) should be caused by the substituted GPD copula as well. This example of real operational loss data might be considered as a warning, not to underestimate the effects of rare events that nevertheless might occur simultaneously.

In cases of no existing theoretical expected shortfall, Moscadelli [28] suggests the risk measure median shortfall (MS) that is defined regardless of the values of the shape parameter \(\xi\). If the respective distribution function is continuous, the median shortfall has the representation

\[
\text{MS}(\alpha) = \text{VAR}\left(\frac{1 + \alpha}{2}\right),
\]

see Biagini and Ulmer [5], pages 749–750. In addition to our previous results, Table 6 states the estimates for the median shortfall, which we computed as \(\hat{\text{MS}}(\alpha) = \hat{\text{VAR}}\left((1 + \alpha)/2\right)\).

Unlike the expected shortfall, the median shortfall as a robust measure is not as heavily influenced by extreme values in the upper tail. Therefore, the median shortfall estimates for \(L(1), L(2)\) are closer to each other than the expected shortfall estimates if we compare
Table 6. Estimated median shortfall

| α   | 95%  | 99%  | 99.5% | 99.9% | 95%  | 99%  | 99.5% | 99.9% |
|-----|------|------|-------|-------|------|------|-------|-------|
| L(1)| 19829| 49196| 78678 | 243938| 19829| 49650| 80292 | 313246|
| L(2)| 21494| 83414| 162438| 793252| 21600| 84386| 162866| 782938|
| L   | 40340| 131267| 234910| 962458| 42463| 127042| 229260| 1085283|

Figure 1. $10^4$ random deviates of $(L(1), L(2))$ based on the original $t$ copula (left) and on the GPD copula (right).

the $t$ copula case with the GPD copula case. However, the values for the median shortfall of $L$ at the 99.9% level do clearly differ, indicating a small number of extreme high losses in the upper tail – in accordance with our considerations on the expected shortfall, see page 18.

To give visual insight into these results, Figure 1 compares the realizations of $X = (L(1), L(2))$ graphically. The graphics were taken from a single simulation that contributed to the results in Table 4 and Table 5. Although the $t$ copula itself is already heavily tailed, the substitution of its upper part by a GPD puts even more weight on observations that are very high in both components. (Recall Corollary 2.2.) The latter type of modelling, therefore, represents a higher risk of an extraordinarily high total loss over a one-year time horizon. This can be seen on the point in the upper right corner in the right scatterplot of Figure 1, which represents a fictive total loss of 6275000, whereas the highest total loss in the respective pure $t$ copula scenario is 3313000.

5. Conclusions

In the present paper we extended the well known univariate PT approach to higher dimensions. This was motivated by Theorem 2.1 and Corollary 2.2, which show that it is
not sufficient to apply the univariate approach to the marginal distributions of a random vector if the upper tail of its distribution is to be modeled adequately. It is, therefore, necessary to approximate the underlying copula by a multivariate GPD.

The multivariate PT approach that was introduced in (9) offers a wide range of scenarios to be modeled because it depends basically only on some random vector whose components need to be bounded and to have expectation one; see Proposition 2.4. As a consequence we also mentioned a natural way to map the set of copulas to the set of multivariate GPDs that was useful for our simulation studies to obtain a one-parametric model.

Because the values in a simulation are random, simulations occur that produce no values that are high in both components. (This is depending on the sample size, too.) Fixing this disadvantage is subject to further research and could probably be achieved by making additional restrictions on the GPD copula random vector in (9). Furthermore, goodness-of-fit testing of the compound GPD copula is required.

Nevertheless, the multivariate PT approach is a powerful and suitable tool to adequately model multivariate distributions in their upper tails. This ensures that the probability of very rare events that occur simultaneously and have a high effect if they occur is not underestimated. The high empirical expected shortfalls in Table 4 might be considered as a warning.

Acknowledgements

The authors are grateful to the referees for their constructive comments on an earlier version of this paper. The authors are also indebted to the SAS Institute, Heidelberg, for providing access to the database SAS OpRisk Global Data.

The first author was supported by DFG Grant FA 262/4-1.
