Abstract

Introduction: Lipomas are rarely encountered in the thoracic cavity. A pleural origin of lipoma is extremely rare. In fewer occasions it infiltrates the intercostal space and has an hourglass development. Therefore, the intrathoracic and extrathoracic dumbbell-shaped lipoma is a very rare finding.

Case Presentation: We present the case of a 77-year-old Caucasian woman with an hourglass-shaped lipoma originating from the left parietal pleura and passing outside the thorax through the first intercostal space. The one-year follow-up revealed no changes.

Conclusions: Intrathoracic and extrathoracic hourglass type lipomas are a very rare pathology. When they occur, a non-surgical approach may be adopted as long as compression symptoms are absent and the follow-up imaging examinations reveal no lesion growth. In our case, the patient’s history and the imaging investigations support the benign nature of the tumor. Particularly, in our case, the size of the lipoma was small compared to the long duration of its evolution and there were no signs and symptoms of intra-thoracic compression. The taken therapeutic approach complies with the patient’s options and fits in the current generally accepted recommendations.

Keywords: Thoracic Lipoma, Hourglass Lipoma

1. Introduction

Lipomas are the most common benign tumors of the soft tissues. They are generally distributed in the subcutaneous areas of the body, but they may develop in all organs throughout the body. In the thoracic cavity, lipomas are rarely encountered. A pleural origin of lipoma is extremely rare (1). The incidence of pleural lipomas is not yet fully known. However, Jensen reported three cases of intrathoracic lipoma from a series of 3,502 cases of thoracic tumors (2) and Jaile reported five cases of intrathoracic lipoma from a series of 1800 patients who were undergoing thoracic exeresis (1). The hourglass-shaped thoracic lipomas are very rarely found (3-5). In his study, Ono identified 22 hourglass type lipomas from 114 cases of intrathoracic lipomas (6).

2. Case Presentation

We present the case of a 77-year-old Caucasian woman, non-smoker, who had signs and symptoms of acute tracheo-bronchitis (fever and cough with muco-purulent expectoration for a few days).

The clinical examination indicated a 6cm-diameter anterior upper-left thoracic mass, painless, soft, non-adherent to the skin, with normal superjacent tissues. The patient observed a slowly progressive growth of it in the last 30 years. She did not have any major complaints related to the tumor. The patient’s body mass index was 31.25 kg/m².

Laboratory examination showed leukocytosis with neutrophilia and elevated levels of C-reactive protein.

On the chest radiography (X-ray), a round opacity was observed in the left lung, projected on the topography of the anterior segment of the upper lobe (Figure 1).

A computed tomography (CT) examination revealed an hourglass-shaped well-defined formation under the left clavicula, with fatty densities (-110 UH) and fine septa inside. The overall dimensions were 73 × 55 × 55 mm [anterior-posterior (AP)-transverse (T)-cranial-caudal (CC)]. Intravenous contrast medium injection provided no contrast enhancement. The formation extended into the chest, exerting a mass effect on lung parenchyma, with a perilesional atelectasis area. Intrathoracic dimensions were 47 × 47 × 41 mm (AP-T-CC). No rib erosion or destructive bone changes were observed (Figures 2 and 3).
Badescu C et al.

Figure 1. The chest X-ray of a 77-year-old non-smoker Caucasian woman. She was admitted to the hospital with signs and symptoms of acute tracheo-bronchitis. Chest X-ray showed a round opacity projected on the topography of the anterior segment of the upper lobe of the left lung. The patient had no complaints related to the tumor. According to the patient, the tumor appeared 30 years ago and was slow in growth.

These findings were consistent with typical lipoma of the extrapleural fat.

Figure 2. CT images (axial view) demonstrating the hourglass-shaped mass of fatty density (-110 UH), homogeneous, without contrast enhancement (arterial phase).

At the time, the patient refused any invasive approach. No biopsy or surgical excision was performed. After one year, a new chest X-ray was performed. No changes were observed (Figure 4). No significant anomalies were reported clinically and biologically. The patient still refused any intervention on the thoracic tumor.

Figure 3. Three dimensional (3D) reconstruction of CT images, showing the passage of the tumor through the first intercostal space.

3. Discussion

Lipomas are common benign tumors of mesenchymal origin, slow-growing, well-defined and encapsulated (7). More than half of lipomas are distributed ubiquitously in the subcutaneous areas of the body, but they may develop in virtually all organs throughout the body.

A variety of lipoma exists. The vast majority are classic...
lipomas and consist only of mature adipose tissue. Some of them contain scattered fibrous connective tissue septa. The superficial classic lipomas are better circumscribed and smaller than the deeper lesions. The deep lipomas are far rarer. Because of the usual detection at a late stage of development, they tend to be larger than superficial ones. They are usually encountered in the chest wall, hand and feet. The variable shape is determined by the space they occupy, because they are forced to mold themselves around the surrounding tissues (8). Extremely rare, classic lipomas can arise on the surfaces of bone (parosteal lipoma) (9).

Rarer types of lipoma contain fat and nonadipose elements in varying proportions. Some of them have similar characteristics to malignant tumors of the soft tissue and pose real problems in diagnosis. Well-differentiated liposarcomas resemble lipomas on both CT and magnetic resonance imaging (MRI) (10, 11). These tumors do not metastasize. Instead, they locally recur after surgical removal and they may undergo dedifferentiation into a more aggressive and potentially metastasizing form of sarcoma (8, 12). Therefore, a thorough pathological examination is imperative. Sometimes a malignant component is difficult to exclude even on biopsy specimens (9, 13).

A lipomatous malignancy does not usually grow in the subcutaneous region; therefore, a deep-seated lipoma, including an intrathoracic lipoma, must be carefully differentiated from malignancies such as liposarcomas or metastatic lesions.

Lipomas are rarely encountered in the thoracic cavity and may originate from the diaphragm, mediastinum, bronchus, lung or thoracic wall (14, 15). A pleural origin of lipoma is extremely rare. It originates in the adipocytes of the visceral, parietal, thoracic or mediastinal pleura (1) and in rare occasions, it can infiltrate the intercostal space. An hourglass development through the intercostal space is possible, however the intrathoracic and extrathoracic dumbbell-shaped lipoma is a very rare finding (9).

Keeley and Vana (16) and Williams and Parsons (17) divided intrathoracic lipomas into two classes: (a) hourglass or dumbbell-shaped lipomas that pass through the thoracic inlet or intercostal space and (b) purely intrathoracic lipomas (9).

In our case, the hourglass-shaped lipoma originated from the left parietal pleura and passed outside the thorax through the first intercostal space. Intrathoracic, it exerts mass effect on the lung parenchyma, with the constitution of perilesional small atelectatic areas. The extrathoracic part of the lipoma exerts mass effect on the muscles. There is no CT evidence of rib erosion or local invasion.

Our patient was asymptomatic like most patients (except a small and painless bump on the anterior upper-left thoracic wall), but since lipomas are able to grow to a large size, non-specific symptoms due to compression may develop, depending on sites and sizes of the tumor mass. Compression symptoms are intermittent cough, mild chest pain, dyspnea, dysphagia or thoracic tightness sensation.

Between simple lipomas and well-differentiated liposarcomas there are major differences concerning treatment, prognosis and long-term follow-up, so it is mandatory to properly distinguish before surgery.
marginal excision is used to treat simple lipomas, while wide local excision is necessary for well-differentiated liposarcomas due to the high probability of local recurrence. A long-term follow-up is also required for well-differentiated liposarcomas because they may dedifferentiate after 5 to 10 years from the initial surgery (18, 19).

On the chest radiography, intrathoracic lipomas look like nodules or masses with rounded and smooth appearance. Unfortunately, conventional radiography cannot be used alone as an imaging method to separate benign from malignant pleural processes, nor to distinguish between pleural processes and parenchymal ones (9).

The modern diagnosis of intrathoracic lipomas is based on CT and MRI. These imaging methods allow the precise localization of the tumor and give information regarding the shape, homogeneous fat content, lack of vascularization and the relationship with nearby structures.

Classic lipomas consist only of mature adipose tissue, therefore they have CT imaging signal characteristics similar to those of subcutaneous fat. One can often identify a thin capsule and less than 2 mm thick septa. Simple lipomas may also contain muscle fibres, blood vessels and necrotic or inflammatory areas (12), making diagnosis more difficult because they mimic findings associated with well-differentiated liposarcomas. The CT diagnostic criteria for lipoma are: well-defined mass of homogeneous fat (-50 to -150 HU), absence of enhancement by an intravenous injected contrast medium, obtuse angles with the chest wall, displacement of the adjacent pulmonary parenchyma and blood vessels.

The therapeutic approach has not yet reached a unanimous consensus. Because lipomas are benign tumors, a nonsurgical approach may be reasonable as long as the imaging examinations reveal no lesion growth. In elderly and frail patients, if the pleural lipomas are small and asymptomatic, the clinical and radiological follow-up may be a good therapeutic option (9). The indication for surgery is a matter of debate (1). In the past, surgery was not usually indicated, except when the tumor was large and caused compression symptoms. Today most authors advocate surgical removal of the intrathoracic lipomas because the possibility of underdiagnosed liposarcoma. In our case, considering the benign CT appearance of the tumor and taking into account the patient's option, we proceed by imaging follow-up.

3.1. Conclusions

Intrathoracic lipomas are not a common pathology, much less the intrathoracic and extrathoracic hourglass type. The history of our patient, the imaging investigations (serial chest X-ray, and CT scan) support the benign and lipomatous nature of the tumor. In our case, the small size of the lipoma compared to the long duration of its evolution and the absence of any signs and symptoms of intrathoracic compression was detected. So, a non-surgical approach could be safely adopted in this case. The taken therapeutic approach complies with the patient's options while fitting in the current generally accepted recommendations.

3.2. Implication for Health Policy Makers/Practice/Research/Medical Education

The etiologic diagnosis of a lung opacity triggers a chain of complex investigations. The result is sometimes surprising. In our case, the opacity has proven to be a dumbbell-shaped lipoma.
