(Received 2 July 2002 published 26 February 2003)

We reexamine the problem of the "Loschmidt echo" that measures the sensitivity to perturbation of quantum-chromatic dynamics. The overlap squared \( M(t) \) of two wave packets evolving under slightly different Hamiltonians is shown to have the double-exponential initial decay \( \exp[-\text{constant} \times e^{2\lambda t}] \) in the main part of the phase space. The coefficient \( \lambda_\text{eff} \) is the self averaging Lyapunov exponent. The average decay \( \bar{M} \propto e^{-\lambda t} \) is single exponential with a different coefficient \( \lambda_1 \). The volume of phase space that contributes to \( \bar{M} \) vanishes in the classical limit \( \hbar \to 0 \) for times less than the Ehrenfest time \( \tau_E = \frac{1}{2} \lambda_\text{eff}^{-1} |\ln \hbar| \) It is only after the Ehrenfest time that the average decay is representative for a typical initial condition.

\[
M(t) = \left| \langle \psi_0 | e^{(\hat{H} + \delta \hat{H}) t / \hbar} e^{-\hat{H} t / \hbar} | \psi_0 \rangle \right|^2
\]

(1)

is not constrained by unitarity Jalabert and Pastawski [4] discovered that \( M(t) \) (which they referred to as the "Loschmidt echo") decays \( \propto e^{-\lambda t} \) if \( \psi_0 \) is a narrow wave packet in a chaotic region of phase space, providing an appealing connection between classical and quantum chaos.

One particularly fruitful line of research goes back to the proposal of Schack and Caves [2], motivated by earlier work of Peres [3], to characterize chaos by the sensitivity to perturbations. Indeed, if one and the same state \( \psi_0 \) evolves under the action of two different Hamiltonians \( \hat{H} \) and \( \hat{H} + \delta \hat{H} \), then the overlap

\[
M(t) = \left| \langle \psi_0 | e^{(\hat{H} + \delta \hat{H}) t / \hbar} e^{-\hat{H} t / \hbar} | \psi_0 \rangle \right|^2
\]

(1)

is not constrained by unitarity Jalabert and Pastawski [4] discovered that \( M(t) \) (which they referred to as the "Loschmidt echo") decays \( \propto e^{-\lambda t} \) if \( \psi_0 \) is a narrow wave packet in a chaotic region of phase space, providing an appealing connection between classical and quantum chaos.

The discovery of Jalabert and Pastawski gave a new impetus to what Schack and Caves called "hypersensitivity to perturbations" of quantum-chromatic dynamics. The present paper differs from this body of literature in that we consider the statistics of \( M(t) \) as \( \psi_0 \) varies in the chaotic phase space. We find that the average decay \( \bar{M}(t) \propto e^{-\lambda t} \) is due to regions of phase space that become vanishingly small in the classical limit \( \hbar \to 0 \). The effective Planck constant \( \hbar_{\text{eff}} = \hbar / S_0 \) is set by the inverse of a typical action \( S_0 \). The dominant decay is a double exponential \( \propto \exp[-\text{constant} \times e^{2\lambda t}] \), so it is truly hypersensitive. The slower single-exponential decay is recovered at the Ehrenfest time \( \tau_E = \frac{1}{2} \lambda_{\text{eff}}^{-1} |\ln \hbar| \).

Before presenting our analytical theory, we show in Fig. 1 the data from a numerical simulation that illustrates the hypersensitivity mentioned above. The Hamiltonian is the quantum kicked rotor [1]

\[
\hat{H} = \frac{\hat{p}^2}{2} + K \cos x \sum_\delta \delta(t-n) \frac{\hbar}{i} \frac{d}{dx}
\]

(2)

The perturbed Hamiltonian \( \hat{H}' = \hat{H} + \delta \hat{H} \) is obtained by the replacement \( K \to K + \delta K \). The coordinate \( x \) is periodic, \( x = x + 2\pi \). To work with a finite dimensional Hilbert space, we discretize \( x = 2\pi \lambda / N, \lambda = 1,2, \ldots, N \). The momentum \( p_m = \hbar \lambda \) is a multiple of \( \hbar \), to ensure single valued wavefunctions. For \( \hbar = \hbar_{\text{eff}} = 2\pi / N \) the restriction to the first Brillouin zone results in a single band \( p_m = 2\pi mN, m = 1,2, \ldots, N \). The time evolution \( e^{-i\delta \hat{H} t} \) after \( n \) periods, of the initial Gaussian wave packet \( \psi_k = e^{-i\phi} \exp(\pi N^{-1/2} \cos(2\pi \lambda / N)(k-k_0)^2) \), is given by the Floquet operator in the \( x \)-representation

\[
U_{x,k} = \frac{1}{\sqrt{N}} \exp \left( -i \pi (k-k')^2 / N - \frac{NK}{2\pi} \cos \frac{2\pi k}{N} \right)
\]

(3)

We use the fast Fourier transform algorithm to compute \( U^n \) for \( N \) up to \( 10^6 \) [6].

FIG 1 The overlap \( M(t) \) for the quantum kicked rotor for three different ways of averaging \( \bigcirc \bigcirc \bigcirc \exp(\ln M) \). We took \( K = 10, \delta K = 6 \times 10^{-3}, N = 10^6 \). Averages are taken over 2000 random initial conditions of a Gaussian wave packet. The dotted line shows the Lyapunov decay \( \propto e^{-\lambda_1 t} \) with \( \lambda_1 = 1.1 \). At \( n = 3 \), we have only an upper bound for the logarithmic averages because cancellations in the calculation limit the accuracy.
We study the statistics of $M(t)$ by comparing in Fig. 1 three different ways of averaging over initial positions $(m_0, \delta x_0)$ of the Gaussian wave packet. We used $K = 10$, $\delta K = 6 \times 10^{-3}$, and $N = 10^6$ ($h_{eff} = 6.28 \times 10^{-6}$). While the average $\bar{M}$ decays exponentially, the two logarithmic averages have a much more rapid initial decay. We estimate that $M < 10^{-21}$ at $n = 3$ for about $30\%$ of randomly chosen initial conditions. For the same point $n = 3$, only $9\%$ of initial conditions (corresponding to $M > 0.2$) account for $80\%$ of the total value of $\bar{M}$. The typical decay of $M(t)$ is therefore much more rapid than the exponential decay of the average $\bar{M}$.

Statistical fluctuations also affect the decay rate of $\bar{M}$ set by the Lyapunov exponent according to Ref. [4]. The definition of the Lyapunov exponent

$$\lambda_0 = \lim_{\tau \to t} -\frac{1}{\tau} \ln |\delta x(t)/\delta x(0)|$$

gives $\lambda_0 = -1.65$ for the classical kicked rotator with $K = 10$. However, $\bar{M}(t)$ in Fig. 1 has exponent $\lambda_1 = 1.1$, defined by

$$\lambda_1 = -\lim_{\tau \to t} -\frac{1}{\tau} \ln |\delta x(t)/\delta x(0)|^{-1}$$

Since fluctuations of $t^{-1} |\delta x(t)/\delta x(0)|$ decrease like $t^{-1/2}$, the Lyapunov exponent $\lambda_0$ is self-averaging [7], while the $\lambda_1$'s are not.

For an analytical description, we start from the Gaussian one-dimensional wave packet

$$\psi(x) = \left(\frac{\alpha}{\pi\hbar}\right)^{1/4} \exp\left(\frac{ip_0x}{\hbar} + (ib - \alpha) \frac{(x - x_0)^2}{2\hbar}\right)$$

The wave packet is centered at the point $x_0(t), p_0(t)$ which moves along a classical trajectory. Initially, $\beta(t = 0) = 0$ and $\alpha(t = 0) = 1$. Divergence of trajectories leads to the exponential broadening of the packet, thus $\alpha(t = \tau) \sim e^{-2K\tau}$. Since $\alpha < 1$ for $t > \tau_0/\alpha$, the wave packet in phase space becomes highly elongated with length $l = \sqrt{\hbar(1 + \beta^2)/\alpha}$ and width $l_\perp = h/l_0$. The parameter $\beta = \Delta x/\Delta x_\perp$ represents the tilt angle of the elongated wave packet [8].

The Gaussian approximation (5) breaks down at the Ehrenfest time $\tau_E = \frac{1}{2} \lambda^{-1} |\ln \hbar|$ when $l_\perp$ becomes of the order of the size of the system. We assume that $\psi$ evolves according to Hamiltonian $H(K)$ and $\psi'$ according to $H' = H(K + \delta K)$. The overlap $M = |\langle \psi|\psi' \rangle|^2$ of the two Gaussian wave packets is

$$M = \left|\frac{\alpha a'}{\alpha^2 + 4b^2} \exp\left(\frac{-\alpha (\beta', \beta) \delta x^2}{2(\alpha^2 + 4b^2)\hbar} - \frac{\alpha a' \delta x^2}{2\hbar}\right)\right|^2$$

When $\delta x_k < 1$, the displacement vector $(\delta x, \delta p)$ has component $\Delta_k = \delta K e^{\Delta t}$ parallel to the elongated wave packets and component $\Delta_\perp = \delta K$ perpendicular to them (see Fig 2).

Depending on the strength of perturbation, one may distinguish three regimes: $\delta K < \hbar, \hbar < \delta K < \sqrt{\hbar}$, and $\delta K > \sqrt{\hbar}$. We will consider in detail the intermediate regime $\hbar < \delta K < \sqrt{\hbar}$ and discuss the two other regimes more briefly at the end of the paper (the simulations of Fig 1 are at the upper end of the intermediate regime, since $\delta K = 1.6 \times 10^{-3}$ and $\sqrt{\hbar} = 2.5 \times 10^{-3}$). The three regimes may be characterized by the relative magnitude of the Ehrenfest time $\tau_E$ and the perturbation dependent time scale $\tau_0 = \frac{1}{2} \lambda^{-1} |\ln \delta K|$. In the intermediate regime, one has $\frac{1}{2} \tau_E < \tau_0 < \tau_E$.

To estimate the relative magnitude of the two terms in the exponent of Eq. (6), we write

$$\delta p - \hat{\beta} \delta x = (1 + \beta^2)\Delta_\perp = \delta \delta K, \quad \text{(7)}$$

$$\frac{-\alpha}{\alpha^2 + 4b^2} = \frac{Q}{1 + (ge^{2\lambda t}/\delta K)^2} \quad \text{(8)}$$

Here, $f$ and $g$ are functions of the order of unity of time $\tau$ and the initial location $x, p$, of the wave packet. The second term in the exponent (6) is of the order $\sqrt{\alpha} \delta x/\hbar = \delta \delta K/\hbar$, which is of the order of the term $Q \delta K^2/\hbar$ in the exponent (7) is of the order $Q \delta K^2/\hbar$. Since $Q \gg 1$ for $t < 2\tau_0$, we may neglect the second term relative to the first term within the entire range $t < \tau_E$ of validity of the Gaussian approximation. Equation (6) simplifies to

$$M = (\bar{a}Q)^{1/2} \exp\left(-\frac{1}{2} Q(f \delta K)^2/\hbar\right) \quad \text{(9)}$$

We seek the statistics of $M(t)$ generated by varying $x, p$. The statistics is nontrivial because fluctuations in $f$ of the order of unity cause exponentially large fluctuations in $\bar{M}$. We will consider in detail the intermediate regime (5), which is the case for $2\tau_0 < \tau_0 < \tau_E$. The average of $\bar{M}$ is then dominated by the nodal lines $x_k(p)$ in phase space at which $f$ vanishes (at a particular time $t$). If $\Delta x_k$ is the typical spacing of these lines at constant $p$, then the derivative $\delta f/\delta x$, at $x_k$ is of order $1/\Delta x_k$. This yields

$$M = (\bar{a}Q)^{1/2} \int dx/\Delta x_k \exp\left[-\frac{(x-x_k)^2}{2(\Delta x_k)^2}\right] Q f^2/2h$$

$$= (\bar{a}Q/\delta K)^{1/2} (\sqrt{h}/\delta K)^{-\lambda/2} \quad \text{(10)}$$

Assuming independent fluctuations in the perturbation dependent distribution of nodal lines and in the rate of diver-
HYPERSENSITIVITY TO PERTURBATIONS OF

Hence, we incorporate fluctuations in \( \lambda \) in Eq (10) via \( \exp(-\lambda t) \rightarrow \exp(-\lambda_0 t) \), in accordance with Eq (4). Hence, we recover the exponential decay of the Loschmidt echo [4], although with the exponent \( \lambda_0 \) instead of \( \lambda_0 \) (in agreement with the numerical results of Fig 1). The exponential decay sets in for \( t \gg 2 \tau_0 \), while for shorter times, \( M \) remains close to unity [9].

The volume \( V \) of phase space near the nodal lines contributing to \( M \) is of the order \( V = (\pi/\delta K)^2/2 \). This volume decreases exponentially in time for \( t < \tau_0 \), reaching the minimal value \( V_0 = \sqrt{\hbar/\delta K} \ll 1 \) at \( \tau_0 \). For larger times, \( V \) increases saturating at a value of the order of unity at \( \tau_E \). We, therefore, conclude that the average \( \bar{M} \) is only representative for the typical decay, if \( t > \tau_0 \). For smaller times, the average is dominated by rare fluctuations that represent only a small fraction of the chaotic phase space.

To obtain an average quantity that is representative for a typical point in phase space, we take logarithmic averages of Eq (9). For \( t > \tau_0 \), one has

\[
\ln \bar{M} = -(\delta K^2/\hbar)\exp(2\lambda_0 t),
\]

\[
\ln(1/\bar{M}) = 2\lambda_0 t - \ln(\hbar/\delta K^2) + O(1)
\]

(The coefficient \( \lambda_0 \) in \( \ln \bar{M} \) appears because we average the square of displacement.) The double logarithmic average (12), given by the self-averaging Lyapunov exponent \( \lambda_0 \), is least sensitive to fluctuations and is representative for the main part of phase space. The typical overlap thus has the double-exponential decay

\[
M = \exp[-\text{const} \times (\delta K^2/\hbar) e^{2\lambda_0 t}],
\]

down to a minimal value \( M_0 = \exp(-\delta K^2/\hbar) \) at \( t = \tau_0 \).

The initial decay (13) for \( t \ll \tau_0 \) is the same as obtained in Ref [10] for the classical fidelity (defined as the overlap of two classical phase space densities). In that problem, the role of \( \hbar \) is played by the initially occupied volume of phase space. A superexponential decay of the classical fidelity has also been obtained by Eckhardt [11].

The origin of the decay (13) is illustrated in Fig 2. For \( t < \tau_0 \), the wave packets are nearly parallel (\( \delta \theta \ll \alpha \)), displaced laterally by an amount \( \Delta \parallel \delta K \). Then the average is an exponential function \( \exp(-\Delta^2/\hbar) \), where the width \( \Delta \parallel \) of each wave packet decreases exponentially in time \( \propto e^{-\lambda t} \).

Hence, we obtain the double-exponential decay

For \( t > \tau_0 \) (when \( \delta \theta \gg \alpha \)), the overlap of the two wave packets is dominated by their cross-paths, \( \delta \phi \). The overlap \( M = \exp(-\text{const} \times |x - x_0|^2/\hbar^2/2) \) now increases with time because \( |x - x_0|^2/\hbar^2 = \Delta \parallel \delta K \). The resulting points fall outside the range of validity of the Gaussian approximation unless \( |f| \ll 1 \) (The result (10) is justified because it is dominated by nodes of \( f \), but we cannot use the Gaussian approximation to extend the formula (13) for the typical decay to \( t > \tau_0 \)). The typical decay and the average decay become the same at \( \tau_E \), so the typical \( \bar{M} \) should in principle remain close to its minimal value \( M_0 \) at \( \tau_0 \) to the value \( M_E \).

FIG 3 Two perturbed wave packets in phase space for \( \tau_E < t < \tau_E + 2 \tau_0 \). The lines show \( p(x) \) (solid) and \( p'(x) \) (dashed) extracted from the Husimi function evolved with the quantum kicked rotator, for \( N = 10^6 \), \( K = 7 \), \( \delta K = 0.1 \), \( n = 5 \). Dots show the crossing points \( x_i \) that contribute to the overlap in stationary phase approximation

\[
\phi = \sum_k \sqrt{p_k} e^{i\sigma_k \hbar} p' = d \sigma_k / d \lambda
\]

For \( \delta K \gg \hbar \), the overlap of two oscillating wave functions \( \phi_1 \), \( \phi' \) of the form (14) may be found in a stationary phase approximation, the stationary points are given by the crossings \( p(x_j) = p'(x_j) \) of the two lines \( p(x_j) \), \( p'(x_j) \) given by the evolution with Hamiltonians \( H, \dot{H}' \). For \( \tau_E < t < \tau_E + 2 \tau_0 \), the number of crossings \( N_c \) is proportional to \( l_{||} \) and independent of \( \delta K \). This is because both the lateral displacement of \( p \) and \( p' \) and their relative angles are of the same order \( \delta K \). (In Fig 3, we have \( l_{||} = 20 N_c \).) Each crossing contributes to \( \langle \psi | \psi' \rangle \), an amount

\[
P_j = \sqrt{p(x_j) p'(x_j)} \int dx \exp \left[ \frac{\kappa(x - x_j)^2}{2\hbar} + i \phi_x \right]
\]

\[
(\exp(i\phi_x - \phi_x')) \sqrt{\hbar / \delta K}
\]

where \( \kappa = d^2 (\sigma - \sigma') / dx^2 \) and \( \hbar \phi_x = \sigma(x_j) - \sigma'(x_j) \).

The phase \( \phi_x \) varies randomly from one crossing to the other, leading to

\[
\bar{M} = \frac{\hbar}{l_{||} \delta K} \sum_{j=-1}^{N_c} e^{i(\phi_x - \phi_x')} = \frac{\hbar}{l_{||} \delta K} \frac{\hbar}{\delta K} e^{-\lambda_0 t}
\]

Due to the large number of crossings, there is now little difference between \( \bar{M} \) and logarithmic averages. For \( t > \tau_E + 2 \tau_0 \), the number of crossings becomes \( N_c = \delta K l_{||}^2 \). (The distance between almost parallel segments of \( p'(x) \) of the
order $|II|$, and the line $p(x)$ crosses at the angle $\delta K$ about $K_{\text{th}}=1$ segments per unit length.) This leads to saturation of the overlap at $\hat{M}=\hbar$.

This completes our discussion of the intermediate regime $h<\delta K<\sqrt{\hbar}$. We conclude with a brief discussion of the other regimes. For $\delta K>\sqrt{\hbar}$, the longitudinal displacement of the packets exceeds their lengths, $|\Delta|>l$. The logarithmic averages now remain the same, but $\hat{M}$ is changed. The dominant contributions to $\hat{M}$ are now given by the late events for which both $\Delta_\perp$ and $\Delta_\|\perp$ vanish. This leads to

$$M \sim (h/\delta K)^2 e^{-\chi} \times 11$$

for $t<2\tau_0$. (The same Lyapunov decay as in the intermediate regime, but with a much smaller prefactor.)

For $\delta K<\hbar$, the longitudinal displacement of the packets exceeds their lengths, $\Delta_\|>l$. The overlap then becomes

$$M \sim h/\delta K$$

In this time range, the average overlap has a plateau at $\hat{M}=\hbar/\delta K$. Finally, for $t>\tau_E$, the decay (16) $M \sim (\hbar/\delta K)^2 e^{-\chi/11}$ is recovered.

In the remaining regime $\delta K<\hbar$, we find from Eq. (6) that $M(t)$ remains close to unity for $t<\tau_E$, regardless of the initial location of the wave packet. This also results in insensitivity of the way of averaging. The golden-rule decay [5], with rate $\Gamma=\delta K/\hbar$, sets in only after the Ehrenfest time $\hat{M}=\exp[-\Gamma(t-\tau_E)]$ for $t>\tau_E$. These results are depicted in Fig. 4. The golden-rule decay persists until the Heisenberg time $t_H=1/\hbar$ or the saturation time $\Gamma^{-1}||\ln\hbar||$, whichever is smaller. (Only the initial decay is shown in Fig. 4.) The Gaussian decay [5] sets in for $t>\tau_H$, provided that $\delta K<\hbar$.

In summary, we have shown that statistical fluctuations play a dominant role in the problem of the Loschmidt echo on time scales below the Ehrenfest time. While the decay of the squared overlap $M(t)$ of two perturbed wave packets is exponential on an average, as obtained previously [4], the typical decay is double exponential. It is only after the Ehrenfest time that the main part of the packet follows the single-exponential decay of $\hat{M}$. The Ehrenfest time has been heavily studied in connection with the quantum-to-classical correspondence [5]. The role that this time scale plays in suppressing statistical fluctuations has not been anticipated in this large body of literature.
