Campylobacter is a major food-borne pathogen in humans, and previous studies reported a high prevalence of gentamicin-resistant Campylobacter isolates from food-producing animals in China. This study aimed to investigate the aminoglycoside resistance of Campylobacter isolated from chicken and swine in Jiangsu province, China and understand the possible mechanisms responsible for aminoglycoside resistance. One hundred and eighty-five Campylobacter isolates of chicken and swine origins in 2017 and 2018 were analyzed for gentamicin and kanamycin resistance. Some aminoglycoside resistance genes were selected for PCR detection in all strains. The genomic DNAs of two strains with high resistance to gentamicin were used as donors to subject C. jejuni NCTC11168 to natural transformation. The transformants were investigated by whole-genome sequencing and analyzed comparatively with C. jejuni NCTC11168. In total, 30.5% (29/95) of C. jejuni isolates and 42.2% (38/90) of C. coli isolates were resistant to gentamicin and kanamycin. The prevalence of the aph(2")-Ia and aac(6')-Ie/aph(2")-Ia gene was 65.4% (121/185) and 36.2% (67/185) in Campylobacter isolates, respectively. The aadE-sat4-aphA-3 cluster was identified in 8.7% (8/92) and 20.4% (19/93) of all Campylobacter isolates in each year. With each donor DNA, aminoglycoside-resistant transformants were obtained. The transformants showed ≥128-fold increases in the MICs of gentamicin, kanamycin, and tobramycin. A 5200-bp segment was found to be inserted between the highly conserved genes Cj0299 and panB of Campylobacter. A total of 9.7% (18/185) strains showing high resistance to aminoglycosides had this segment by PCR detection. The genetic diversity of the insertion-fragment positive strains was determined by MLST, and seven sequence types were identified for these strains.

Keywords: Campylobacter, aminoglycoside resistance, natural transformation, MLST, Food Safety
INTRODUCTION

Campylobacter jejuni and Campylobacter coli are the main pathogens that cause sporadic gastroenteritis worldwide (Costa and Iraola, 2019; Man, 2011). In 2010, Campylobacter was estimated by laboratory confirmation to cause the highest number of food-borne bacterial infections globally (Noordhout et al., 2017). With a laboratory-modified isolation kit based on a membrane filter method (ZC-CAMPY-002, Qingdao Sinova Biotechnology Co., Ltd., Qingdao, China) has been extensively used to isolate Campylobacter from diarrheic patients in China CDC’s surveillance project, the Campylobacter isolation in sporadic diarrheal cases significantly increased (Li et al., 2018). But compared with other countries, the outbreak caused by Campylobacter in China is rare (Li et al., 2020). Most Campylobacter enteritis cases are usually mild and self-limiting and do not require antimicrobial therapy; however, for severe or prolonged cases, antibiotic treatment is needed. Fluoroquinolones and macrolides are commonly used to treat campylobacteriosis, but aminoglycosides are used in systemic infections, such as bacteremia (Payot et al., 2006; Blaser and Engberg, 2008). Aminoglycosides are important veterinary antimicrobials in all major food-producing animals to treat infections and are classified by the WHO as important antimicrobials for human medicine (Giguère et al., 2013; World Health Organization, 2019). The extensive use of antibiotics in food-animal production has led to an increase in antimicrobial-resistant strains of Campylobacter (Alfredson and Korolik, 2007).

Among the known mechanisms of acquired aminoglycoside resistance, the enzymatic modification is the most common mechanism for the inactivation of aminoglycosides in many bacterial species, including Campylobacter spp. (Vakulenko and Mobashery, 2003; Ramirez and Tolmasky, 2010). The aminoglycoside-modifying enzymes are divided into three main classes based on the reactions they catalyze: aminoglycoside acetyltransferases (AAC), aminoglycoside nucleotidyltransferases, and aminoglycoside phosphotransferases (APH) (Ramirez and Tolmasky, 2010). Numerous aminoglycoside resistance genes have been reported on mobile genetic elements and transposons (Lee et al., 2002; Nirdnoy et al., 2005). Gentamicin resistance genes including aacA4, the bifunctional gene aac(6′)-Ie/aph(2′)-Ia (also named acaA-aphD), aph(2′′)-Ie, and aph(2′′)-Ig have been detected in Campylobacter (Chen et al., 2013; Zhao et al., 2015). A unique genetic structure containing the aminoglycoside resistance gene cluster aadE-sat4-aphA-3 and aacA-aphD has been identified on the chromosome of C. coli (Qin et al., 2012). Recently, a high prevalence and predominance of the aph(2′′)-Ie gene has been reported in Campylobacter (Yao et al., 2017). The aph(2′′)-Ie shows resistance to gentamicin and other aminoglycosides, such as kanamycin, sisomicin, and tobramycin (Toth et al., 2013). A novel streptomycin resistance gene has also been described, and its widespread presence among C. coli may partly account for the streptomycin resistance (Ollkola et al., 2016).

Gentamicin resistance in Campylobacter isolated from various livestock commodities along the food-producing continuum (“farm to fork”) and in humans is rare and stable in most countries. In Netherlands in 2017, no gentamicin resistance was found in Campylobacter isolates from cattle, pigs, and poultry. The resistance to streptomycin varies between 0 and 2.6% in C. jejuni isolates from broilers (European Food Safety Authority (EFSA), 2017). The level of resistance to streptomycin and gentamicin is low (0–1%) for C. jejuni from broilers and cattle in Denmark (DANMAP, 2019). Based on a report of the National Antimicrobial Resistance Monitoring System, gentamicin resistance in Campylobacter in the United States was rare before 2007 but has increased rapidly and been detected in 12.2% and 18.1% of human isolates and retail isolates, respectively (National Antimicrobial Resistance Monitoring System: Enteric Bacteria, 2011; National Antimicrobial Resistance Monitoring System: Retail Meat Annual Report, 2011). In China, several aminoglycoside agents have been used in conventional broiler and swine productions, and the prevalence of gentamicin-resistant Campylobacter from broiler and swine is much higher than that in the United States. A recent study has shown that over 60% of Campylobacter isolated from swine and chicken are resistant to gentamicin (Yao et al., 2017). Up to 95% of C. coli isolated from chicken and 23% from swine are gentamicin resistant (Chen et al., 2010; Qin et al., 2011; Ma et al., 2014).

In the present study, the prevalence of gentamicin and kanamycin resistance and the associated aminoglycoside resistance genes were analyzed in Campylobacter isolated from chicken and swine in Jiangsu province, China. We found a gene segment which could be transferred from C. jejuni or C. coli to a C. jejuni strain by natural transformation, resulting in a drastic increase in aminoglycoside resistance. These findings suggested that the responsible use of aminoglycosides is highly important in safeguarding public health in China.

MATERIALS AND METHODS

Campylobacter Strains and Aminoglycoside-Susceptibility Testing

A total of 185 Campylobacter isolates (95C. jejuni and 90C. coli isolates) was investigated in this study. All Campylobacter isolates were recovered in 2017 and 2018 from cloacal swabs of chickens and feces of swine from Jiangsu province, eastern China, during our laboratory annual antimicrobial resistance surveillance program. Strains in 2017 were isolated from chicken cloacal swabs and chicken meat: 67 Campylobacter strains from chicken cloacal swabs (samples number = 150) and 25 Campylobacter strains from chicken meat (samples number = 80). The strains in 2018 were isolated from chicken cloacal swabs and pig animal feces: 73 Campylobacter strains from chicken cloacal swabs (samples number = 150) and 22 Campylobacter strains from pig fresh feces (samples number = 100). Chicken cloacal swabs were collected from 15 chicken farms in each year. From each farm, 10 cloacal swabs were taken from randomly selected animals. Chicken meat samples were collected from 16 supermarkets located in seven districts in Jiangsu Province. From each supermarket, five chicken meat samples were selected randomly. The pig fresh feces were collected from randomly selected animals in 10 pig farms located in Jiangsu province. All isolates were frozen at −80°C in a brain heart infusion broth with 20% glycerol. Campylobacter were
grown on Mueller Hinton (MH) agar (Difco, MD, United States) supplemented with 5% sheep blood under microaerophilic conditions (85% nitrogen, 10% carbon dioxide, and 5% oxygen) at 42°C. The MICs of gentamicin and kanamycin for Campylobacter were determined by the standard agar dilution method according to the guidelines of the (Clinical and Laboratory Standards Institute, 2016). The isolates which showed resistance to gentamicin and kanamycin were further examined for their susceptibility to amikacin, tobramycin, and streptomycin. The reference strain C. jejuni ATCC 33560 was used as a quality-control strain. The above experiments were repeated twice to confirm the reproducibility of the MIC data. The CLSI MIC interpretive criteria for resistance of antimicrobial agents were used. Antimicrobial agents were obtained from the Biomed Biotecnology Company.

Identification of Aminoglycoside Resistance Genes in Campylobacter Isolates

The known aminoglycoside resistance genes aph(2”)-If, aacA4, and aac(6’)-Ie/aph(3’)-Ia, as well as the aade-sat4-aphA-3 gene cluster, were selected for PCR detection in all strains. Genomic DNA was isolated from the strains by using a TIANamp Bacteria DNA purification kit (TIANGEN, Beijing, China). Amplifications were carried out in a 25 μl PCR mixture composing 12.5 μl of Ex-Tag (Takara, Dalian, China), 1 μl of each primer, 1 μl of chromosomal DNA template, and 9.5 μl of sterile distilled water. The amplifications were carried out on a thermal cycler using the following parameters: 94°C for 5 min, followed by 30 cycles of 94°C for 40 s, annealing temperature specific to the primer pair for 30 s and 72°C for 1.5 min, and final extension at 72°C for 10 min. The primers of these genes and the annealing temperatures for the different target genes are listed in Table 1. The amplified products were separated by gel electrophoresis on 1.0% agarose gels, stained with GelRed, and visualized under UV light.

Natural Transformation and Whole-Genome Sequencing

A natural transformation assay was performed according to the method described by Wang and Taylor with minor modifications (Wang and Taylor, 1990). The genomic DNAs of aminoglycoside-resistant Campylobacter isolates served as the donors, whereas the aminoglycoside-sensitive strain of C. jejuni NCTC11168 served as the recipient. In a typical procedure, the fresh recipient cells were spread on MH agar containing 5% sheep blood and cultured for 6–8 h (at 42°C under microaerobic conditions). Then, 1 μg of genomic DNA of the donor strain was added to the inoculated agar followed by 5 h of continuous incubation at 42°C under microaerobic conditions. The cells were harvested and plated on the selective MH agar plate containing kanamycin (60 μg/ml), and the plate was further cultured for 48–72 h at 42°C under microaerobic conditions. The recipient without donor DNA cultured on the same MH agar served as a negative control. Single colonies of transformants were selected and sub-cultured on gentamicin-containing plates for purity. The MICs of the aminoglycoside (gentamicin, kanamycin, amikacin, tobramycin, and streptomycin) resistance for the transformants were determined by the standard agar dilution method according to the guidelines of the CLSI (Clinical and Laboratory Standards Institute, 2016). Subsequently, two transformants were selected for whole-genome sequencing on an Illumina HiSeq 2500 platform (Novogene, Beijing, China). The generated 150 bp pair-end reads were trimmed and quality controlled, and the clean reads were assembled using SPAdes software. The draft genomes of the transformants were compared with NCTC11168 using Mauve.

PCR Detection of the Insert Fragment

According to the insertion site of the fragment, the primers were synthesized following a previous method (Yao et al., 2017) (Table 1). The unknown insertion fragment was detected in Campylobacter isolates by PCR. The EmeraldAmp PCR Master Mix (RR300A) (TaKaRa, Dalian, China) was composed of 12.5 μl of Hot start DNA polymerase, 1 μl of each primer, 1 μl of chromosomal DNA template prepared as previously described, and 9.5 μl of sterile distilled water. PCR was carried out according to the instructions of RR300A. The PCR products were separated as described above.

MLST and Aminoglycoside-Susceptibility Analysis of Insertion-Fragment Positive Isolates

MLST analysis of insertion-fragment positive Campylobacter strains was performed following a previously described method (Dingle et al., 2005). DNA was extracted from the selected strains by using a commercial DNA Kit (Tiangen Biotech Inc., Beijing, China). Primer sequences were obtained from http://pubmlst.org/Campylobacter. The nucleotide sequences of the amplicons were determined by Sangon Biotech (Shanghai, China). Allele numbers and sequence types (STs) were assigned using the Campylobacter PubMLST database. Subsequently, the resistance to multiple aminoglycoside antimicrobials of the insertion-fragment positive strains was investigated.

RESULTS

Aminoglycoside Resistance in Campylobacter Isolates

A total of 36.2% (67/185) Campylobacter isolates was resistant to both gentamicin and kanamycin. Among the 92 Campylobacter isolates tested in 2017 (C. jejuni, 51; C. coli, 41), 28 (30.4%, including 13C. jejuni and 15C. coli) were resistant to the above two antibiotics. However, in 2018, among 93 Campylobacter isolates tested (C. jejuni, 44; C. coli, 49), 39 (41.9%, including 16C. jejuni and 23C. coli) showed resistance to these two drugs. The proportions of gentamicin and kanamycin-resistant Campylobacter strains ranged from 28.1% to 60.0% among the seven regions. The rate of resistance of Campylobacter to gentamicin and kanamycin in 2018 was higher than that in 2017. A higher
percentage of *C. coli* than *C. jejuni* isolates was resistant to gentamicin and kanamycin (Table 2). The distributions of gentamicin MICs of gentamicin-resistant *Campylobacter* are shown in Figure 1, which revealed that the strains with an MIC value of 128μg/ml accounted for a large proportion.

### Presence of Aminoglycoside Resistance Genes

Various aminoglycoside resistance genes were examined by PCR in all 185 *Campylobacter* isolates. The prevalence of the *aph(2’)-Ia* gene was 57.6% (53/92) and 73.1% (68/93) in *Campylobacter* isolates in 2017 and 2018, respectively. Moreover, *aph(2’)-Ib* gene was more prevalent in *C. coli* than in *C. jejuni* in 2017. Similar to the *aph(2’)-Ib* gene described above, *aadA*-Ia/*aph(2’)*-Ia gene was identified in 31.5% (63.4% in *C. coli* and 5.9% in *C. jejuni*, 2017) and 40.9% (49.0% in *C. coli* and 31.8% in *C. jejuni*, 2018), showing its common presence and higher prevalence in *C. coli*. Among all gentamicin-resistant strains, 44.8% (30/67) contained two of the resistant genes, and 14.9% (10/67) did not have any of these four tested genes. The prevalence of the *aadE*-sat4-aphA-3 cluster in *Campylobacter* isolates was identified to be ≤10% in 2017, but it increased to about 20% in 2018 (Table 2).

### Transfer of Aminoglycoside Resistance Through Natural Transformation

The genomic DNAs of the two strains with high resistance to gentamicin (*C. jejuni* 165 and *C. coli* 254) were used as the donor DNA to transform the recipient strain (*C. jejuni* NCTC11168) by natural transformation under laboratory conditions. Compared with NCTC11168, the transfectants NT-165 and NT-254 were obtained, showing 512- and 128-fold

| Total |                     | 16/44 (36.4) | 23/49 (46.9) | 4/44 (9.1) | 15/40 (30.6) | 38/44 (84.4) | 30/49 (61.2) |
|      |                     | 39/93 (41.9) | 19/93 (20.4) | 68/93 (73.1) | 38/93 (40.9) | 67/85 (36.2) |
increases in the MICs of gentamicin, kanamycin, and tobramycin, respectively. The transformant NT-254 showed slightly decreased susceptibility to amikacin. However, the transformant NT-165 did not show any resistance to amikacin or streptomycin. The MICs of gentamicin, kanamycin, tobramycin, amikacin, and streptomycin in the recipient, donors, and transformants are revealed in Table 3.

The two transformants were then investigated by whole-genome sequencing. Subsequently, the draft genomes of NT-165 and NT-254 were compared with NCTC11168, showing that the backbones of the transformants were NCTC11168. Moreover, a 5,200-bp segment was inserted between the Campylobacter highly conserved genes Cj0299 and panB. The same insertion region was already identified in 2017 (Yao et al., 2017). The inserted segment contained six open reading frames (ORFs). It included genes encoding AAC/APH (a bifunctional enzyme), dTDP-fucosamine acetyltransferase, cytidylate kinase, IS1595 family transposase, and two hypothetical protein genes (Figure 2). Combined with the MICs results of the transformants above, it suggested that the six-gene cluster can transferred among Campylobacter strains naturally, and it conferred a high-level resistance to aminoglycoside antibiotics.

Molecular Typing and Aminoglycoside Resistance of the Insertion-Fragment Positive Campylobacter Isolates

Using the primers cj0299-F and panB-R, a 5.2-kb fragment was amplified in 9.7% (18/185) Campylobacter isolates. Some examined isolates, including aminoglycoside-resistant isolates and susceptible ones, did not yield this 5.2-kb fragment but showed a 750-bp fragment (Figure 3). These positive strains originated from five different locations in Jiangsu province (Table 4). Subsequently, the resistance to multiple aminoglycoside antimicrobials of the insertion-fragment positive strains was investigated. Most strains showed high MICs to gentamicin and kanamycin. About 72.2% (13/18) showed high MICs to all five tested aminoglycosides (Table 4).

To understand if the insertion-fragment positive isolates were genetically related, 18 isolates above were selected for MLST analysis. Seven STs were identified for these strains: a new ST (165 in location HA), ST860 and ST829 (254 and 53–1, respectively, in location HA), ST10062 (246 in location YC and 55–1, 58–3, 58–4, 58–6, 58–8, 61–4, 62–2, and 62–4 in location YZ), ST1666 (59–2 in location YZ), ST9627 (1–1, 1–2, 2–1, and 2–2 in location CZ), and ST832 (52–1 in location NT). Except for a new ST and ST10062 strains whose clonal complexes were not assigned, others belonged to clonal complex 828. ST10062 appeared in different years and different locations, although the number of ST10062 strains in 2017 was relatively small (Table 4).

DISCUSSION

Aminoglycosides used in veterinary medicine is associated with increased resistance to aminoglycosides and other antimicrobial classes in bacteria from animals. C. jejuni and C. coli isolates of clinical and animal origin display resistance to aminoglycoside streptomycin (van Duijkeren et al., 2019). In China, antimicrobial use records reveal that aminoglycoside agents, such as amikacin and neomycin, are commonly used to prevent bacterial diseases in food-producing animals (Wang et al., 2016). Although the level of resistance to gentamicin in Campylobacter is low in other countries, an increasing trend has been observed in recent years, and the gentamicin resistance rate of Campylobacter in China has become higher than those in other countries (Zhao et al., 2015; Yao et al., 2017; DANMAP, 2019). In the present study, the prevalence of gentamicin and kanamycin resistance in Campylobacter is ≥30.0%, consistent with previous reports in China (Qin et al., 2012; Ma et al., 2014; Yao et al., 2017). Previous studies have shown that gentamicin resistance is much more prevalent in C. coli than in C. jejuni strains (Wang et al., 2016; Yao et al., 2017). In the present study, a higher percentage of resistance to gentamicin and kanamycin was found in C. coli than in C. jejuni isolates. The resistance to gentamicin and kanamycin
of *C. jejuni* and *C. coli* increased by more than 10.0% in 2018 compared with that in 2017 in Jiangsu province. The increasing trend suggested that we should pay attention to rational drug use and strengthen the monitoring of aminoglycoside drug resistance in China.

Resistance genes can be located on the plasmids, chromosome, transposons, or other mobile elements, increasing the aminoglycoside resistance and the co-resistance to other compounds (Ramirez et al., 2013). There is an apparent trend toward multidrug resistance, particularly among *C. coli* which harbored different antimicrobial resistance genes within the genome of a single isolate (European Food Safety Authority (EFSA), 2019). Four variants of aminoglycoside-resistant genes were analyzed by PCR. The bifunctional enzyme aac(6')-Ie/aph(2")-Ia confers resistance to almost all aminoglycosides except streptomycin (Zhao et al., 2015). In clinical *Enterococcus* isolates, it is the most important enzyme associated with high-level gentamicin resistance (Toth et al., 2013). A previous study has reported the recent emergence of aph(2")-If and has become the predominant gentamicin resistance determinant in *Campylobacter* in Shandong province in China (Yao et al., 2017). In the present study, the prevalence rates of the aac(6')-Ie/aph(2")-Ia gene in *Campylobacter* isolates were 31.5% and 40.9% in 2017 and 2018, respectively. Aph(2")-If gene was also more prevalent in *Campylobacter* herein than in another previous study in China. The reason for the increased prevalence of these two genes may be the different years and regions of the isolated strains. Further studies are needed to show if an annual increasing trend occurs in the presence of these two gentamicin resistance genes.

The gene cluster aadE-sat4-aphA-3, which confers resistance to streptomycin, streptomycin, and kanamycin, has been detected on a plasmid and in the chromosome in *Campylobacter* (Chen et al., 2013; Zhao et al., 2015). It was identified in a *C. coli* genomic island which harbors genes conferring resistance to multiple aminoglycoside antibiotics in China (Qin et al., 2012). The aadE-sat4-aphA-3 gene cluster was observed in about ≤15.0% isolates in the present study. Among all cluster-positive strains, 13 isolates did not show any resistance to gentamicin or kanamycin. This result was not consistent with the previously reported results showing that all clusters carrying *C. coli* were resistant to gentamicin (Qin et al., 2012). But in another paper, the florfenicol-resistant gene cfr(C)-carrying *C. coli* isolates were susceptible to chloramphenicol and florfenicol (Liu et al., 2019). The gentamicin resistance gene aacA4 has been reported in *C. jejuni* isolated from the water lines of a broiler-chicken house environment, and it is associated with class 1 integron (Lee et al., 2002). However, no aacA4 gene was detected in the *Campylobacter* isolates examined in this study, consistent with a previous one (Yao et al., 2017). About 15.0% (10/67) gentamicin-resistant isolates contained none of the above four detected aminoglycoside-resistant genes which may harbor other unknown resistance mechanisms.

*Campylobacter* are well known for their ability to acquire exogenous DNA by natural transformation (Wang and Taylor,
Some genes associated with high-level gentamicin resistance in Campylobacter have probably resulted from horizontal transfer from other microorganisms (Zhao et al., 2015). Herein, transformants with ≥128-fold increase in the MICs of gentamicin were obtained by natural transformation under laboratory conditions. This difference in aminoglycoside MIC values suggested that some genes of the genome were transferred from C. jejuni or C. coli to C. jejuni and intensively increased the aminoglycoside resistance in the recipient strain C. jejuni.

Genomic islands harboring aminoglycoside resistance genes and multidrug resistance have been previously detected between cadF and CCO1582 on the chromosome in C. coli, and multiple aminoglycoside resistance genes have been found to be located between Cj0299 and panB (Qin et al., 2012; Wang et al., 2014; Yao et al., 2017). Herein, we compared the draft genomes of two transformants with NCTC11168 and found a 5,200-bp segment inserted between the highly conserved Campylobacter genes Cj0299 and panB. The presence of this segment was associated with elevated MIC values for aminoglycosides. In recent years, different multidrug resistance genomic islands (MDRGIs) conferring resistance to aminoglycosides, macrolides, and tetracyclines were characterized (Qin et al., 2012; Wang et al., 2014; Liu et al., 2019). Unlike MDRGIs in previous reports, the inserted segment in this study just contained six ORFs (Figure 2). AAC/APH which encoded a bifunctional enzyme was in it. Gene aacA-aphD was the only gene identified to encode a bifunctional aminoglycoside-modifying enzyme responsible for gentamicin and kanamycin resistance in Campylobacter. This insertion fragment could spread by horizontal gene transfer. In 18 insertion-fragment positive strains, about 72.0% (13/18) showed high MICs to all five tested aminoglycosides (Table 4). This result suggested that the insertion fragment was associated with aminoglycoside resistance, the prevalence of which could confer a fitness advantage under selection by continued aminoglycoside usage.

In a previous study, an aminoglycoside resistance island was reported to spread by both horizontal gene transfer and clonal expansion by PFGE and MLST analysis in Shandong province, China (Qin et al., 2012). To understand if the insertion-fragment positive Campylobacter isolates in the present study were genetically related or had any clonal expansion, 18 fragment positive isolates were selected for MLST analysis. Seven STs were identified for these strains. The 18 strains had no particular clonal expansion. Except for a new ST and ST10062 whose clonal complexes had not been assigned, all

other strains belonged to clonal complex 828, consistent with a previous study (Qin et al., 2012). Interestingly, ST10062 appeared in different years and locations. More strains are needed to further determine whether this type of ST is a special clonal expansion for the dissemination of aminoglycoside resistance in China.

CONCLUSION

This study provided the prevalence of gentamicin and kanamycin resistance and the associated aminoglycoside resistance genes in Campylobacter isolated from chicken and swine in Jiangsu province, China. A gene segment which could drastically increase aminoglycoside resistance by natural transformation was found. Owing to the use of aminoglycosides in poultry and swine production, Campylobacter in poultry and swine may be able to deal with the toxicity and selective pressure from these antibiotics. These findings offered insights into the prevalence and spread of the aminoglycoside resistance of Campylobacter in China, thereby highlighting the need for concerning and taking measures to reduce the dissemination of aminoglycoside resistance in Campylobacter.

ETHICS STATEMENT

This study was carried out in accordance with the principles of the Animal Welfare and Ethical Censor Committee of Jiangsu Institute of Poultry Science. No chickens and pigs were killed for the present study. When collecting cloacal swabs, well-trained farm workers hold the chickens. Fresh feces from pigs were collected without any manipulation of the pigs.

AUTHOR CONTRIBUTIONS

QZ, JZ, and JP performed the antibiotic susceptibility tests. XZ and QZ did the aminoglycoside genes detection. MT and XZ performed natural transformation and MLST. YZ and JL did the data analysis. XZ prepared the manuscript. YG supervised and assisted in the manuscript preparation. All authors contributed to the article and approved the submitted version.

FUNDING

This work was supported by Yangzhou social development project (YZZ2020061) and National Natural Science Foundation of China grant (31700005).
