ABSTRACT

Altered sleep architecture and stroke share a reciprocal relationship. More than half of the stroke patients display sleep abnormalities including hypersomnia, insomnia, parasomnia, periodic limb movements, or sleep-disordered breathing. Conversely, one of the major causes of severe organic hypersomnia is acute brainstem strokes, involving thalamic infarctions, which may be reversible over 6–12 months. Here, we report a patient with increased lethargy and drowsiness who was diagnosed to have a right thalamic and hypothalamic ischemic stroke.

KEYWORDS: Drowsiness with stroke, paramedian thalamic stroke, thalamic infarction, thalamic stroke

INTRODUCTION

Sleep architecture consists of nonrapid eye movement (NREM) and REM components which alternate in 90-min cycles. Sleep disorders, including obstructive sleep apnea, daytime hypersomnia, and sleep-disordered breathing, are being increasingly identified as causative factors of both cardiovascular and cerebrovascular diseases. Conversely, central nervous system lesions, including strokes, have been reported to disturb sleep cycle, structure, and pattern leading to changes in the electroencephalography (EEG) and polysomnography recordings. The right hemispheric strokes have been shown to depress REM sleep density with an increase in NREM (particularly NREM 1 and 2) as compared to left hemispheric strokes which reduce the slow-wave sleep (SWS) (NREM 4).[1] Diencephalic lesions, including paramedian thalamic infarctions, cause severe hypersomnia with memory and attention deficits, oculomotor palsies, and mild gait ataxia.[2] Although commonly associated with bilateral lesions, unilateral thalamic strokes are being now reported as a frequent cause of hypersomnia.

CASE REPORT

A 57-year-old right-handed male, previously diagnosed hypertensive, was brought by family members with complaints of being apathetic and having excessive sleepiness for the last 2 days as if he had consumed a bottle full of sleeping pills. Although he could be aroused by minimal stimulus, he preferred to go back to sleep soon. The patient reported that he was not happy with his sleep quality and felt an urge to sleep all the time. There were no other complaints of weakness, sensory symptoms, or memory disturbances. The patient was afibrile, arousable to commands, oriented and was of average built with a body mass index of 25.9 kg/m². Neurological examination was nonsignificant for any lateralizing deficits. Mini-Mental State Examination score was 20/30 with defects in attention and recall. He was evaluated for causes related to metabolic or septic encephalopathy; however, blood parameters were normal. Magnetic resonance (MR) imaging brain showed an acute diencephalic infarct involving the right anterior and paramedian thalamus and the hypothalamus [Figure 1]. MR angiogram of cerebral vessels was normal. EEG done did not show any epileptiform discharges. Evaluation of sleep revealed an Epworth Sleepiness Score of 18. He was managed conservatively and showed symptomatic improvement with improved arousal during follow-up visit after 3 months.

Our patient had a right thalamic stroke leading to a persistent drowsy state with decreased awakening. On 3-month follow-up, he reported significant improvement in his sleep. Bilateral paramedian thalamic infarctions have been well documented to cause hypersonmolence with a dearousal state. However, sleep-wake disturbances following unilateral ischemia are an area of interest.

Bilateral or left thalamic involvement has been shown to predict a poorer recovery when compared to the right thalamic lesions. The poor outcome in the left-sided strokes is associated with lesions of the Papez circuit producing deficits in the frontal lobe-related functions of learning, memory, and language, rather than focal neurological deficits. Right thalamic lesions, on the other hand, have less common cognitive deficits and more complete recovery.

To conclude, thalamic strokes can have protean manifestations ranging from thalamic pain and hemisensory syndrome to excessive sleepiness with attention and cognitive defects. Drowsiness in a stroke patient usually points to large hemispheric strokes with overt neurological deficits. However, in the absence of other focal deficits, it becomes difficult to ascertain the cause of drowsiness or excessive sleepiness to strokes, and most of the evaluation involves testing for metabolic and septic encephalopathies. Hence, it becomes imperative for these patients to undergo neuroimaging to rule out thalamic lesions.

Declaration of patient consent
The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.
