ABSTRACT

Although measuring the gas metallicity in galaxies at various redshifts is crucial to constrain galaxy evolutionary scenarios, only rest-frame optical emission lines have been generally used to measure the metallicity. This has prevented us to accurately measure the metallicity of dust-obscured galaxies, and accordingly to understand the chemical evolution of dusty populations, such as ultraluminous infrared galaxies. Here we propose diagnostics of the gas metallicity based on infrared fine structure emission lines, which are nearly unaffected by dust extinction even the most obscured systems. Specifically, we focus on fine-structure lines arising mostly from H\textsubscript{i}i regions, in photoionization models, we show that the emission-line flux ratio of ([O\textsubscript{iii}]88.33+[O\textsubscript{ii}]38.33)/[N\textsubscript{ii}]57.21 is an excellent tracer of the gas metallicity. The individual line ratios [O\textsubscript{ii}]38.33/[N\textsubscript{ii}]57.21 can also be used as diagnostics of the metallicity, but they suffer a stronger dependence on the gas density. The line ratios [O\textsubscript{iii}]51.80/[N\textsubscript{ii}]57.21 and [N\textsubscript{ii}]121.7/[N\textsubscript{ii}]57.21 can be used to measure and, therefore, account for the dependences on the of the gas density and ionization parameter, respectively. We show that these diagnostic fine-structure lines are detectable with Herschel in luminous infrared galaxies out \(z \sim 0.4\). Metallicity measurements with these fine-structure lines will be feasible at relatively high redshift (\(z \sim 1\) or more) with SPICA, the future infrared space observatory.

Key words. galaxies: abundances – galaxies: evolution – galaxies: general – galaxies: ISM – H\textsubscript{i} regions – infrared: ISM

1. Introduction

The metallicity of gas and stars in galaxies is one of the most important properties to distinguish various galaxy evolutionary scenarios, since metals result from the cumulative star-formation activity and gas inflow/outflow history in galaxies. Since the gas metallicity of galaxies is in most cases much easier to measure than the stellar metallicity, past studies on the metallicity of galaxies and its evolution have mostly focused on the metallicity of the gas phase (e.g., McCall et al. 1985; Zaritsky et al. 1994; Pettini et al. 2001). Several extensive and detailed studies have been performed on the gas metallicity in local galaxies, the connection with other galaxy properties and the metallicity evolution through the cosmic epochs (e.g., Tremonti et al. 2004; Savaglio et al. 2005; Erb et al. 2006; Maiolino et al. 2008; Mannucci et al. 2009, 2010). Such observational studies have provided strong constraints on evolutionary scenarios (e.g., de Rossi et al. 2007; Kobayashi et al. 2007; Brooks et al. 2007; Finlator & Davé 2008).

The vast majority of previous studies on the gas metallicity in galaxies used rest-frame optical diagnostics (see, e.g., Nagao et al. 2006a and references therein). However, such rest-frame optical diagnostics cannot probe the metallicity of the regions affected by significant dust extinction, which is the case for many star forming galaxies, especially at high redshift. This is because the fraction of dusty galaxies such as ultra-luminous infrared galaxies (ULIRGs) increases as a function of redshift (e.g., Le Floc’h et al. 2005). Hence, optical metallicity studies probably probe only the outer, less extinguished region of star forming galaxies, which may deviate substantially from the metallicity of inner more active and more obscured regions of star formation. A clear indication of such a mismatch was recently found in high-z submillimeter galaxies by Santini et al. (2010), who used dust-mass measurements to infer an metals content an order of magnitude higher than inferred from optical metallicity diagnostics. If such mismatch applies to a significant fraction of actively star forming galaxies, this would imply a major revision of the past results on the metallicity evolution in galaxies based on optical diagnostics. Within this context we note that, even for starbursts which have been well-studied in optical, a combination of radio and infrared measurements has conclusively demonstrated that some of the most active star-forming sites are optically obscured (e.g., Gorjian et al. 2001; Vacca et al. 2002; Soifer et al. 2008).
The access to far-infrared diagnostics of the gas metallicity would overcome the dust extinction problems plaguing optical measurements. Observational studies on gas metallicity exploiting infrared indicators have already been carried out by using Infrared Space Observatory (ISO). Verma et al. (2003) investigated mid-infrared spectra of 12 nearby starburst galaxies and found a strong correlation between gas metallicity and gas excitation, which is also seen in some optical studies (e.g., Nagao et al. 2006; Maier et al. 2006). Garnett et al. (2004) studied chemical properties of gas in M51 based on the ISO data and found that the C/O abundance ratio in M51 is consistent with the solar neighborhood value. This infrared-based metallicity studies is expected to progress dramatically by using the on-going and forthcoming observational facilities such as Herschel, JWST, SPICA, and ALMA. Within this context, it is important to investigate in detail model predictions yielding calibrations between the gas metallicity and flux ratios of emission lines at long wavelengths. Motivated by this, we present the results of photoionization model calculations and the theoretical calibrations of gas metallicity diagnostics based on fine-structure emission lines in mid- and far-infrared wavelength ranges.

2. The method

In the mid-infrared to sub-millimeter wavelength range, there are many fine-structure emission lines radiated by various ions in various excitation levels. Although some of them arise within HII regions, some others arise in photo-dissociation regions (PDRs) that surrounds the inner HII regions. For instance the [CII]157.6 emission, that is the strongest emission line in spectra of most galaxies and thus detected even in very distant galaxies (e.g. Maiolino et al. 2005; Iono et al. 2006; Maiolino et al. 2009, Hailey-Dunpheth et al. 2010), is mainly from PDRs rather than HII regions (e.g., Crawford et al. 1985; Stacey et al. 1991). Some emission lines arise both in HII regions and PDRs (e.g., Petuchowski & Bennett 1993; Heiles 1994; Annestad & Emery 2003; Abel 2006). The latter class of lines are the most difficult to model, since they have a more complex dependence on the various physical parameters of the clouds, and therefore they are not ideal metallicity diagnostics. Even lines arising mostly from PDR are not optimal to be used as metallicity diagnostics, since modeling PDRs is very challenging, because involves complex physical mechanisms of the gas heating and of radiative transport. The modeling of HII regions is much more easy and generally more understood and tested; in these regions the dependence of the line emissivity from the various physical parameters is much simpler than in the case of PDRs. As a consequence, lines arising mostly from HII regions are more suitable candidates to measure the gas metallicity of the inter-stellar matter. Therefore, it is very important to understand the emissivity distribution of various fine-structure emission lines in gas clouds and, specifically, understand which ones arise mostly from HII regions and which are instead significantly contributed by PDRs. This is possible by using the publicly available photoionization model code *Cloudy*, as described by Abel et al. (2005, 2006).

We have carried out photoionization model calculations by using *Cloudy* version 08.00 (Ferland et al. 1998; Ferland 2008). We assume pressure-equilibrium gas clouds with a plane-parallel geometry. As described later, the results are not significantly different if we assume constant-density clouds instead of pressure-equilibrium clouds, as far as only HII regions are considered (see §§3.2). Calculations are stopped at the depth where the fraction of the H2 molecule reaches 50% of the total hydrogen, when we investigate lines arising both from HII regions and from PDRs. This depth is defined as the outer edge of PDRs, following Abel et al. (2005). On the other hand, calculations are stopped at the depth where the fraction of H+ reaches down to 1% of the total hydrogen, when the emission lines arising only from HII regions are investigated (§§3.2). We define this depth as the outer edge of HII regions.

Some low-excitation fine-structure lines can arise beyond this outer edge of PDRs (i.e., fully molecular regions surrounding the inner PDRs; see, e.g., Abel et al. 2005). We do not investigate such fully-molecular regions since our main interest in this work is on emission-lines arising within HII regions, as described below.

The free parameters in our calculations are (1) the hydrogen density of a cloud ($n_H$) at the irradiated surface of a cloud; (2) the ionization parameter ($U$), i.e., the ratio of the ionizing photon density to the hydrogen density at the surface of a cloud; (3) the elemental composition of the gas; and (4) the spectral energy distribution (SED) of the

![Fig. 1. SEDs of the ionizing continuum adopted in our photo-ionization models, which are starburst99 constant star-formation model spectra (Leitherer et al. 1999) with an age of 1 Myr and an alpha = 2.35 IMF ($M_{low} = 1M_\odot$ and $M_{up} = 100M_\odot$). Although most of our analysis adopt these spectra, models with different ages (3, 10, and 30 Myr) are investigated in §3.3. The blue, cyan, green, orange, and red spectra denote a model with $Z_{star} = 0.05Z_\odot$, $0.2Z_\odot$, $0.4Z_\odot$, $1.0Z_\odot$, and $2.0Z_\odot$, respectively. The $Z_{star} = 2.0Z_\odot$ spectrum is used also for our $Z_{gas} = 3.0Z_\odot$ calculations (see the main text). All spectra are normalized at 5000Å ($\approx 0.18$ Ryd).](image-url)
Table 1. Adopted solar elemental abundance ratios and gas-phase depletion factors

| element | n/n_H | depletion factor |
|---------|-------|------------------|
| H       | 1.00e+0 | 1.00             |
| He      | 1.03e-1 | 1.00             |

\(^{a}\) See the main text for details of the treatments for helium and nitrogen.

The adopted ionizing continuum radiation. We investigate plane-parallel gas clouds with gas densities \(n_{H} = 10^{1} - 10^{4} \, \text{cm}^{-3}\) at the illuminated face (note that the gas density varies as a function of the depth within gas clouds), and ionization parameters \(U = 10^{-3.5} - 10^{-1.5}\). Here the ionization parameter is a dimensionless parameter defined as follows:

\[
U = \frac{\Phi(H)}{c n_{H}} = \frac{1}{c n_{H}} \int_{n_{1}}^{\infty} \frac{F_{\nu}}{h \nu} \, d\nu
\]

where \(c\) is the speed of the light, \(\Phi(H)\) is the surface flux of hydrogen-ionizing photons, \(F_{\nu}\) is the surface energy flux of the input radiation, and \(n_{1}\) is the frequency of the Lyman edge \((h \nu_{1} = 13.6 \, \text{eV})\).

The adopted solar elemental abundance ratios (in terms of number density, not mass) and gas-phase depletion factors are given for convenience in Table 1. The adopted depletion factors are derived from the literature (e.g., Cowie & Songaila 1986; Jenkins 1987; Cardelli et al. 1991; see Ferland 2006 for more details). However, there is no broad consensus on those factors and, moreover, they may depend on the gas density (e.g., Spitzer 1985). We do not discuss this issue further in this work, and we simply adopt the depletion factors given in Table 1. For non-solar metallicities we assume that both the dust model and the depletion factors are unchanged, but the dust abundances is assumed to scale linearly with the gas metallicity. All elements except nitrogen and helium are taken to be primary nucleosynthesis elements. For helium, we assume a primary nucleosynthesis component in addition to the primordial value, that is,

\[
\frac{n_{He}}{n_{H}} = 0.0737 + 0.0293 \frac{Z_{\text{gas}}}{Z_{\odot}}
\]

(Groves et al. 2004). Nitrogen is assumed to be a secondary nucleosynthesis element above metallicities of 0.23 solar, and a primary nucleosynthesis element at lower metallicities, i.e.,

\[
\log \frac{n_{N}}{n_{H}} = 2 \log \frac{Z_{\text{gas}}}{Z_{\odot}} - 4.070 \quad \text{when } Z_{\text{gas}} > 0.23 Z_{\odot}
\]

and

\[
\log \frac{n_{N}}{n_{H}} = \log \frac{Z_{\text{gas}}}{Z_{\odot}} - 4.709 \quad \text{when } Z_{\text{gas}} < 0.23 Z_{\odot}
\]

(Kewley & Dopita 2002). Note that the behavior of nitrogen as a secondary element (Eq. 3) is observationally confirmed through the data of H\(\alpha\) regions in galaxies (e.g., van Zee et al. 1998; Pilyugin et al. 2003). Chemical evolutionary models of galaxies also predict such a behavior for a wide range of parameters, including variations of the IMF (e.g., Hamann & Ferland 1993; Chiappini et al. 2003). The validity of Eq. 3 is sometimes questioned at very high metallicities, \(Z_{\text{gas}} \geq 5 Z_{\odot}\), which is however beyond the range studied in this work (see, e.g., Nagao et al. 2006b; Jiang et al. 2008). We investigate gas clouds with gas metallicities \(Z_{\text{gas}} \leq 0.05, 0.2, 0.4, 1.0, 2.0, \) and 3.0 times solar metallicity. In the calculations, Orion-type graphite and silicate grains (Baldwin et al. 1991; Ferland 2006), as well as polycyclic aromatic hydrocarbon (PAH), are included.

The adopted ionizing continua are the starburst99 constant star-formation model spectra (Leitherer et al. 1999) with an age of 1 Myr and an \(\alpha = 2.35\) IMF \((M_{\text{low}} = 1 M_{\odot} \text{ and } M_{\text{up}} = 100 M_{\odot})\). We selected these model parameters because, in this work, we want to simulate actively star-forming galaxies (such as infrared galaxies and submillimeter galaxies). However, to demonstrate that our results do not depend on the ionizing continuum shape, we will also investigate models adopting SEDs with older ages (§3.3). The starburst99 spectra are available for stellar metallicities of \(Z_{\text{star}} = 0.05, 0.2, 0.4, 1.0, 2.0,\) and 2.0 times solar metallicity, which are shown in Figure 1. For models with \(Z_{\text{gas}} = 3 Z_{\odot}\), we adopt the starburst99 spectrum with \(Z_{\text{star}} = 2 Z_{\odot}\).

The cosmic background emission from radio to X-ray is also included (see Ferland 2006 for details). However, this component does not affect the calculation results significantly. The heating and ionization by cosmic rays are also included, which affects the thermal solutions especially in the PDRs (see, e.g., Ferland & Mushotzky 1984; Ferland 2006).

3. Results

3.1. Contributions from H II regions and PDRs

We first investigate from which parts of clouds emission lines originate in order to explore optimal emission-line combinations which can be used as good metallicity diagnostics. In Figure 2, we show hydrogen density structures and cumulative intensities of some fine-structure emission...
Fig. 2. Hydrogen density structure (upper panels) and cumulative intensity of some fine-structure emission lines (lower panels) of clouds with $Z_{\text{gas}} = 0.2Z_{\odot}$ (left hand panels) and $Z_{\text{gas}} = 3.0Z_{\odot}$ (right hand panels), as a function of hydrogen column density. For both cases, $n_H = 10^4 \text{ cm}^{-3}$ and $U = 10^{-2.5}$ are adopted (where $n_H$ is the hydrogen density at the illuminated face of clouds). Solid, dashed, and dotted lines in the upper panels denote the densities of $H^+$, $H^0$, and $H_2$, respectively. In the lower panels, solid lines show cumulative intensities for fine-structure emissions mainly from Hii regions while dashed lines are for emissions that are emitted also, or mostly from PDRs.

lines of clouds with $Z_{\text{gas}} = 0.2Z_{\odot}$ and $3.0Z_{\odot}$, as functions of the hydrogen column density. The outer edges of PDRs defined above correspond to the end points of calculations. The outer edges of Hii regions are clearly seen as a sharp drop of the density of $H^+$. It is shown in Figure 2 that relatively high excitation lines such as $[\text{O}III]51.80$ and $[\text{NII}]57.21$ arise within Hii regions while lower excitation lines such as $[\text{O}I]63.17$ and $[\text{Cl}I]157.6$ arise mostly in PDRs.

To see how Hii regions and PDRs contribute to the intensities of various infrared fine-structure emission lines more quantitatively, we give the fraction of the Hii region contribution to total emission-line intensity for the cases of $Z_{\text{gas}} = 0.2Z_{\odot}$ and $3.0Z_{\odot}$, $n_H = 10^{1.0} \text{ cm}^{-3}$ and $10^{3.0} \text{ cm}^{-3}$, and $U = 10^{-2.5}$ and $10^{-1.5}$, in Tables 2 and 3. The following line-intensity emission lines arise within Hii regions without significant contribution from PDRs (see, e.g., Abel et al. 2005).

### 3.2. Metallicity-sensitive emission-line flux ratios

Metallicity diagnostics by using infrared fine-structure lines have been also discussed in some previous studies. The main approach consists in calculating abundances of ionic species directly based on their emissivity. The flux ($F_{X+}$) of a given ionic species ($X^+$) is the product of the density of the ion ($n_{X^+}$), the electron density ($n_e$), and the emissivity of the ion ($j_{X^+}$). Therefore, in Hii regions (where $n_{H^+} \simeq n_H$ by definition), the following relation applies:

$$F_{X^+} = \frac{n_{X^+} \cdot n_e \cdot j_{X^+}}{n_{H^+} \cdot n_{H^+} \cdot j_{H^+}}$$

which can be re-written as

$$\frac{n_{X^+}}{n_H} = \frac{F_{X^+}}{F_{H^+}} \frac{j_{H^+}}{j_{X^+}}$$

where the emissivities are calculated once the gas temperature is known from the photoionization model. Once ionic abundances are inferred by photoionization models,
we can estimate the elemental abundances by applying appropriate ionization correction factors (ICFs). For instance, Verma et al. (2003) derived elemental abundances of Ne from [NeI]12.81 and [NeII]15.56, Ar from [ArII]6.99 and [ArIII]8.99, and S from both [SII]18.71 and [SIV]10.51, by using hydrogen recombination lines such as Brα, for nearby starburst galaxies based on Spitzer spectra (see also Wu et al. 2008). Panuzzo et al. (2003) also investigated the strategy to derive N abundance by using [NiI]121.7, [NiII]57.21, and Brα.

However, the requirement of relying hydrogen recombination lines makes this approach highly uncertain. Indeed, the relatively large wavelength separation between hydrogen recombination lines and metallic emission lines (especially for the case of N) is hard to be covered by the same instrument, and the use of different instruments or facilities may introduce significant systematic errors (due to, e.g., aperture effects and calibration errors) in the estimated metallicities. Moreover, hydrogen recombination lines are sometimes difficult due to the effect of stellar absorption features. In addition, the wavelength of Brα is not long enough to avoid significant dust extinction in many cases, since it is known that the amount of extinction toward the most obscured part of star formation in galaxies can reach up to $A_V \sim 100$ mag (e.g., Verma et al. 2003). Although Panuzzo et al. (2003) discussed the use of the radio continuum emission instead of hydrogen recombination lines to overcome the above difficulties, the radio continuum generally contributed by synchrotron emission, or even an active galactic nucleus, and therefore the relation between the radio continuum flux and the hydrogen line flux may be complicated. Therefore, “good” metallicity diagnostics should consist of fine-structure emission lines (not of hydrogen recombination lines) at long wavelengths, whose wavelength separation is not exceedingly large.

Liu et al. (2001) investigated N/O elemental abundance ratios of 51 Galactic planetary nebulae (PNs) and protoplanetary nebulae (PPNs) with [OIII]51.80, [OIII]88.33, and [NII]57.21. They derived the $N^{2+}/O^{2+}$ ratio and transformed it into the N/O ratio. Here the two [OIII] lines are used to correct for density effects. The combination of these fine-structure emission lines appears to be an optimal set of candidate metallicity diagnostics since all of their wavelength are long enough, and all of them are simultaneously covered by using some observational facilities, such as the Herschel Photodetector Array Camera and Spectrometer (PACS) (although it requires a small redshift of $z \gtrsim 0.08$ to have all lines in band). We therefore focus on this approach and investigate it further below.

In Figure 3, the predicted [OIII]51.80/[NII]57.21 flux ratio is shown as a function of the gas metallicity. It is shown that this flux ratio has a strong metallicity dependence, especially in the high metallicity range ($Z_{\text{gas}} > 0.2Z_\odot$). However, this flux ratio also displays (smaller) dependences on the ionization parameter and on the gas density, which prevent to accurately infer the gas metallicity. Figure 4 shows the predicted flux ratios of [OIII]88.33/[NII]57.21, as a function of the gas metallicity. Again we see the density effects on the flux ratio. Note that models with a lower gas density predict larger flux ratios of [OIII]88.33/[NII]57.21, that is in an opposite trend from the case of [OIII]51.80/[NII]57.21 (Figure 3).

The diagnostic accuracy improves significantly if the sum of [OIII]51.80 and [OIII]88.33 is used instead of only
Fig. 6. Predicted emission-line flux ratio of [Neiii]12.81/[Neii]15.55 (upper) and [Nii]121.7/[Nii]57.21 (lower) as a function of the density-sensitive flux ratio [Oiii]51.88/[Oii]88.33. Solid and dotted lines denote $U$-constant and $n$-constant model sequences, respectively. Models with $Z_{\text{gas}} = 0.2$, 1.0, and 3.0 $Z_\odot$ are denoted by blue, green, and red lines, respectively. The models with $Z_{\text{gas}} = 0.2Z_\odot$ or with $n_H = 10^4$ cm$^{-3}$ are not shown in the lower panel because [Nii]121.7 is extremely faint in those cases. Observational data for M82 and for the Antennae galaxy are shown in the lower panel.

[Nii]51.80, as shown in Figure 5. The density effect on the flux ratio of ([Oiii]51.80+[Oii]88.33)/[Nii]57.21 is small ($\lesssim 50\%$) over the whole range of metallicities. However, there is still a significant dependence on the ionization parameter, especially at high-metallicities ($Z_{\text{gas}} \gtrsim 2Z_\odot$), where it may cause variation of the ratio up to a factor of $\sim 3$. We will compare these model predictions with observational data in §§4.1.

The predicted fluxes of Hii region lines are summarized in Table 4, where they are normalized by the [Oiii]51.88 flux. The results do not change significantly when we adopt constant-density models instead of constant-pressure models. More specifically, the differences in the predicted fluxes of the emission lines given in Table 4 between constant-pressure models and constant-density models are less than 20% in most cases.

Next we focus on how to account for the dependence of the ionization parameter of the flux ratios shown in Figures 3, 4, and 5. To estimate the ionization parameter, pairs of ion species of the same element in a different ionization degree have been often used. We thus examine two flux ratios of [Neii]12.81/[Neii]15.55 and [Nii]121.7/[Nii]57.21 as possible tools to correct for the ionization parameter effect. Note that also [Neii]12.81 and [Nii]121.7 are HII region lines (i.e. not from PDRs), as described in §§3.1. In Figure 6, we show these two emission-line flux ratios as a function of the density-sensitive flux ratio [Oiii]51.80/[Oii]88.33. Clearly, both of the two flux ratios are strongly dependent on the ionization parameter and therefore they can be used to measure $U$ and correct the metallicity diagnostic flux ratio ([Oiii]51.80+[Oii]88.33)/[Nii]57.21 for this dependence. These two flux ratios are also sensitive to metallicity, that is partly due to the metallicity-dependent SED of the ionizing photons (Figure 1). Therefore an iterative process is required to estimate metallicity of galaxies by using the diagnostic diagrams given in Figures 5 and 6. Which is the $U$-sensitive flux ratio more appropriate to correct for the ionization parameter effects on the metallicity determination depends on the specific case. The [Neii]12.81 and [Neii]15.55 emission lines are moderately strong in star-forming galaxies and have been observed by Spitzer in many galaxies (e.g., Dale et al. 2006), and their flux ratio has only a slight dependence on the gas density, as shown in Figure 6. However, these lines are more affected by dust extinction effect with respect to the metallicity diagnostic emission lines, [Oiii]51.80, [Oii]88.33, and [Nii]57.21. In contrast, [Nii]57.21 and [Nii]121.7 do not suffer significant dust extinction. However, the expected emissivity of [Nii]121.7 is low, which makes its measurement challenging. In Figure 7, we also plot the same $U$-sensitive flux ratios, [Neii]12.81/[Neii]15.55 and [Nii]121.7/[Nii]57.21 as a function of the density-sensitive flux ratio [Nii]121.7/[Nii]205.4, instead of [Oiii]51.80/[Oii]88.33. Since the [Nii]205.4 emission is very faint and at a very long wavelength, it is very difficult to study with Herschel and SPICA, though its detection should be feasible with ALMA.

3.3. Dependences on the stellar age

All emission-line flux ratios shown in Figures 3–7 are calculated by adopting constant star-formation SEDs with an age of 1 Myr. However, it should be verified whether the predicted flux ratios depend on the age of the stellar population since the adopted age (1 Myr) seems too young compared to the typical age of star-forming galaxies in general. Cid Fernandes et al. (2003) investigated stellar populations of nearby starburst galaxies and reported that the typical starburst age is $\sim 10^7$–$10^8$ yr. More recently, Rodríguez Zaurín et al. (2010) studied stellar populations of low-$z$ ULIRGs, finding similar age ranges. It is thus important to examine how the emission-line diagnostics studied in this work depend on the age of the stellar populations used for the input SED.

We calculated the emission-line flux ratios of ([Oiii]51.80+[Oii]88.33)/[Nii]57.21 and [Nii]121.7/[Nii]57.21 by adopting the input SED of
stellar populations with ages of 3, 10, and 30 Myr in addition to our default value (1 Myr). Figure 8 shows the results of the age dependences of those two diagnostics. The flux ratio of ([OIII]51.80+[OIII]88.33)/[NII]57.21 changes by less than 30% in the range 1−30 Myr, that is negligible with respect to the metallicity dependence of this flux ratio shown in Figure 5. The age dependence is not significant also for the flux ratio [NII]121.7/[NII]205.4.

These results are due to the fact that the SED shape significantly changes as a function of the stellar-population age (for the range of 1−30 Myr) only at λ > 3000Å (see Figure 8 in Leitherer et al. 1999), when the constant star-formation history is assumed. The SED at shorter wavelengths does not significantly depend on the starburst age, because in that wavelength range it is dominated by emission from massive stars. Since the ionization structure in HII regions is mostly determined by ultraviolet photons (whose SED is not sensitive to the stellar-population age), the flux ratios of HII-region lines are consequently insensitive to the starburst age. These situation may be completely different for PDR lines such as [CII]157.6, but the age dependence of such PDR lines is beyond the scope of this work. Note that the constant star-formation history is a better assumption than the single-burst model for star-forming galaxies when relatively old ages (∼30 Mye) are assumed, because stellar populations with an age of ∼30 Myr in the single-burst model do not produce ionizing photons and thus we do not expect detectable emission-line fluxes from such systems. It can be therefore concluded that our analysis on metallicity (and other) diagnostics does not significantly depend on the age of stellar populations.
4. Discussion

4.1. Comparison with observational data

Here we compare our calculation results on long-wavelength ($\lambda > 50$ $\mu$m) diagnostic fine structure lines with existing observational data. The only previous instrument that measured the diagnostic fine-structure lines in star-forming galaxies is LWS onboard ISO. Specifically we focus on two galaxies, M82 and the Antennae galaxy, since many infrared fine-structure lines are measured for them (Fischer et al. 1996; Colbert et al. 1999). The measured fluxes are summarized in Table 5. Interestingly, the measured flux ratio of [O\textsc{iii}]51.80/[O\textsc{iii}]88.33 is quite similar between those two galaxies; 1.2 and 1.0 for M82 and the Antennae. These flux ratios correspond to $n_H \sim 10^{2}$ cm$^{-3}$ for $U \lesssim 10^{-2}$ (Figure 5). The metallicity diagnostic flux ratio of ([O\textsc{iii}]51.80+[O\textsc{iii}]88.33)/[N\textsc{ii}]57.21 is also similar between M82 and the Antennae, 5.6 and 6.0 respectively. Taking the inferred gas density also into account, these flux ratios correspond to $Z \sim 0.5 - 0.7Z_\odot$, i.e., slightly sub-solar metallicities. The observed flux ratio of [N\textsc{ii}]121.7/[N\textsc{ii}]57.21 in M82 is measured to be 0.5, which, combined with the our initial metallicity estimation, gives log $U = -3.5$. Only an upper limit of [N\textsc{ii}]121.7/[N\textsc{ii}]57.21 < 0.28 (3 $\sigma$) is reported for the Antennae galaxy, providing an upper limit on log $U$ of about $-3$. Although the constraint on the ionization parameter is not strong, the uncertainty on the ionization parameter does not affect significantly the metallicity estimation.

Although both M82 and the Antennae are well-studied nearby galaxies, it is not so straightforward to compare the inferred gas metallicity based on the fine-structure emission-line flux ratios with that inferred from other metallicity diagnostics, because the aperture size of LWS (the beam-size is $\sim 80$ arcsec in FWHM) is very large and difficult to compare with other measurements. Origlia et al. (2004) measured the nuclear gaseous and stellar metallicities by using X-ray and near-infrared spectroscopic observations, and they found that both these metallicities are close to or slightly less than the solar metallicity in M82. Taking the metallicity gradient into account, these metallicities (based also on diagnostics little affected by dust extinction) are consistent with the metallicity inferred through the far-IR fine-structure diagnostics. The situations is similar also for the Antennae galaxy, since its gaseous and stellar metallicities are close to or slightly less than the solar metallicity (Bastian et al. 2006, 2009). Although the comparisons discussed above do not provide a tight test for our new metallicity diagnostics based on far-IR fine structure lines, do at least suggest a broad consistency with other metallicity diagnostics.

4.2. Observational feasibility with next-generation instruments

We finally examine the detectability of the diagnostic fine-structure emission lines discussed here with the new-generation instruments, PACS on Herschel (Poglitsch et al. 2010) and SAFARI (Swinyard 2008; Swinyard et al. 2009) the spectrometer planned for SPICA (a 3m-class cooled telescope in space, Nakagawa 2009). Figure 9 shows the detectability of [N\textsc{ii}]121.7, [N\textsc{ii}]57.21, [O\textsc{ii}]51.80, and [O\textsc{ii}]88.33 with PACS. Specifically the figure shows the

**Fig. 9.** Detectability with PACS on Herschel of some diagnostic far-IR fine-structure lines discussed in this paper, which can be used to measure the gas metallicity, ionization parameter and density in galaxies, as a function of redshift.

**Fig. 10.** Same as Figure 9 but for the detectability with SAFARI boarded on SPICA.
minimum far-infrared luminosity of galaxies to have each far-IR line detected (S/N=5) with a 3 hour exposure, as a function of redshift. Here we make the simplifying assumption that the luminosity of these emission lines scales roughly with far-infrared luminosity and keeping a ratio similar, on average, to what observed in some nearby galaxies where all of these transitions were observed with past ISO observations; more specifically, $L_{\text{[OIII]88.33}}/L_{\text{FIR}} \sim 1.8 \times 10^{-3}$, $L_{\text{[OIII]51.80}}/L_{\text{FIR}} \sim 1.8 \times 10^{-3}$, $L_{\text{[NII]82.15}}/L_{\text{FIR}} \sim 6.0 \times 10^{-4}$, and $L_{\text{[NII]121.7}}/L_{\text{FIR}} \sim 2.7 \times 10^{-4}$ (Fischer et al. 1996; Colbert et al. 1999). The scale on the right hand side gives the minimum SFR corresponding to the minimum $L_{\text{FIR}}$, by using the SFR-$L_{\text{FIR}}$ relationship given in Kennicutt (1999). Figure 9 suggests that we can detect all the fine-structure emission lines needed to infer the metallicity, in luminous infrared galaxies ($L_{\text{FIR}} \sim 10^{11} - 10^{12}L_\odot$) at redshifts up to $z \sim 0.4$. The detection to somewhat higher redshift is restricted to ULIRGs ($L_{\text{FIR}} > 10^{12} L_\odot$). On the other hand, SAFARI onboard SPICA will drastically expand the detectability, as shown in Figure 10. By using SAFARI, the diagnostic fine-structure lines will be detectable for star-forming galaxies at $z \sim 1$ or at even higher redshift. In Figure 10 we adopt the SAFARI sensitivity given by Swinyard (2008) with a scaling of sensitivity for a conservative 3.0m aperture. Actually the redshift limit may be limited not by the instrument sensitivity, but by the wavelength coverage, although the instrument design of SAFARI has not yet completely fixed.

5. Summary

Gas metallicity diagnostics with infrared fine-structure emission lines are investigated in this paper, based on detailed photoionization model calculations. The main results are as follows:

- Some fine-structure lines arise both in HII regions and PDRs and thus only emission lines arising within HII regions (not in PDRs) should be used as good metallicity diagnostics.
- Emission-line flux ratios that consist of $[\text{OIII}]51.80$, $[\text{NII}]57.21$, and $[\text{OIII}]88.33$ provide good metallicity diagnostics: especially the flux ratio of $([\text{OIII}]51.80+[\text{OIII}]88.33)/[\text{NII}]57.21$ is sensitive to the gas metallicity with a small dependence on the gas density.

Since the infrared fine-structure emission lines are not affected by the dust extinction, the gas-metallicity diagnostics presented in this paper are useful to assess the chemical properties in dust-obscured populations such as infrared galaxies, that are very important in terms of the galaxy evolution. Some of the infrared fine-structure emission lines from high-$z$ galaxies will be apparently exciting targets also for ALMA.

a Total hydrogen density at the illuminated surface, in units of cm$^{-3}$.

Table 5. Measured fluxes of infrared fine-structure lines in M82 and the Antennae galaxy

| line         | M82$^b$               | Antenna$^c$                  |
|--------------|-----------------------|------------------------------|
| $[\text{O III}]51.80$ | $10.3 \pm 0.5 \times 10^{-18}$ | $4.9 \pm 0.29 \times 10^{-19}$ |
| $[\text{N II}]57.21$ | $3.4 \pm 0.5 \times 10^{-18}$ | $1.6 \pm 0.058 \times 10^{-19}$ |
| $[\text{O III}]88.33$ | $8.6 \pm 0.4 \times 10^{-18}$ | $4.7 \pm 0.13 \times 10^{-19}$ |
| $[\text{N II}]121.7$ | $1.7 \pm 0.3 \times 10^{-18}$ | $< 0.44 \times 10^{-19}$ (3$\sigma$) |

a Line fluxes are given in units of W cm$^{-2}$.
b Data taken from Colbert et al. (1999).
c Data taken from Fischer et al. (1996).
