Gene Therapy Rescues Cardiac Dysfunction in Duchenne Muscular Dystrophy Mice by Elevating Cardiomyocyte Deoxy-Adenosine Triphosphate

Stephen C. Kolwicz, Jr., PhD, John K. Hall, PhD, Farid Moussavi-Harami, MD, Xiolan Chen, PhD, Stephen D. Hauschka, PhD, Jeffrey S. Chamberlain, PhD, Michael Regnier, PhD, Guy L. Odom, PhD

HIGHLIGHTS
- rAAV vectors increase cardiac-specific expression of RNR and elevate cardiomyocyte 2-dATP levels.
- Elevated myocardial RNR and subsequent increase in 2-dATP rescues the performance of failing myocardium, an effect that persists long term.

Duchenne muscular dystrophy (DMD) and its milder and allelic form, Becker muscular dystrophy (BMD), are the most frequent muscular dystrophies, occurring once in ~5,000 male births, and are due to mutations in the dystrophin gene (1). DMD patients typically die due to cardiac and respiratory muscle failure; thus, maintenance of adequate function in both cardiac and skeletal muscle is critical for optimal DMD therapy. The primary function of dystrophin is to provide a structural role by mechanically linking the subsarcolemmal cytoskeleton to the extracellular matrix through the dystrophin-glycoprotein complex (DGC) (2). This linkage transmits the forces of contraction to the extracellular matrix and protects muscles from contraction-induced injury (3–7). In addition to a structural or mechanical role, the DGC also serves as a scaffold for cytoplasmic and membrane-associated signaling proteins and ion channels (8–11). The complete absence of dystrophin results in drastic reductions of all DGC components (12–14). Together, an absence of dystrophin and reduction in the DGC components causes membrane destabilization and permeability defects that lead to myofiber degeneration, repeated cycles of degeneration/regeneration, and the gradual replacement of muscle fibers with fibrotic, connective, and adipose tissue.

In contrast, some in-frame deletions, truncations, and missense mutations lead to reduced dystrophin expression associated with milder phenotypes. These

- We show the ability to increase both cardiac baseline function and high workload contractile performance in aged (22- to 24-month old) mdx4cv mice, by high-level muscle-specific expression of either microdystrophin or RNR.
- Five months post-treatment, mice systemically injected with rAAV6 vector carrying a striated muscle-specific regulatory cassette driving expression of microdystrophin in both skeletal and cardiac muscle, exhibited the greatest effect on systolic function. In comparison, mice treated with rAAV6 vector carrying RNR that expresses exclusively in cardiac muscle not only exhibited greatly improved baseline systolic function but also improved diastolic function.
- Importantly, vector-directed overexpression of RNR did not impair cardiac reserve during increased physiological demand in aged mdx4cv hearts.

**SUMMARY**

Mutations in the gene encoding for dystrophin leads to structural and functional deterioration of cardiomyocytes and is a hallmark of cardiomyopathy in Duchenne muscular dystrophy (DMD) patients. Administration of recombinant adeno-associated viral vectors delivering microdystrophin or ribonucleotide reductase (RNR), under muscle-specific regulatory control, rescues both baseline and high workload-challenged hearts in an aged, DMD mouse model. However, only RNR treatments improved both systolic and diastolic function under those conditions. Cardiac-specific recombinant adeno-associated viral treatment of RNR holds therapeutic promise for improvement of cardiomyopathy in DMD patients. pathologies are largely curtailed in mouse (mdx) and canine (cxdm) models of DMD following the vector-mediated delivery of muscle-specific expression of highly functional miniaturized versions of dystrophin, microdystrophin (µDys) (15-24). In mdx mice, muscle pathology is milder than in humans, with the exception of the diaphragm; however, the dystrophic phenotype worsens with increasing age including the development of cardiac dysfunction (25-32). Administration of recombinant adeno-associated viral (rAAV)-mediated µDys therapy in mdx mice preceding the onset of cardiomyopathy is highly cardioprotective (33-35). However, when mdx mice are treated with µDys at a late stage of cardiomyopathy, such as would be the case for a number of DMD patients, a full rescue of the dysfunctional cardiac phenotype is not achieved (30,35-37).

**METHODS**

**ANIMAL EXPERIMENTS.** Male WT C57Bl/6J (The Jackson Laboratory, Bar Harbor, Maine) and mdx⁴cv (generated in-house) mice were used for these studies (17). All animals were experimentally manipulated in accordance with the Institutional Animal Care and Use Committee of the University of Washington. Experimental mice were administered vector at 22 to 24 months of age via the retro-orbital sinus with a 200-µl bolus injection in Hanks balanced saline solution at a dose of 2 × 10¹⁴ vg/kg. All mice were housed in a specific-pathogen free animal care facility using a 12-h light/12-h dark cycle with access to food and water ad libitum.

**VECTOR PRODUCTION.** rAAV genomes containing the CK8 regulatory cassette (expressed exclusively in skeletal and cardiac muscle) and the human codon optimized (GenScript) µDys (ΔR2-15/ΔR18-22/ΔCT) (24), followed by the rabbit beta-globin poly-adenylation (pA) signal, were generated using standard cloning techniques. The rAAV genomes containing the cardiac muscle-specific cTnT455 regulatory cassette, the codon optimized human RNR transgene flanked by 100-bp untranslated regions, and the rabbit beta-globin pA were generated as previously described (48). The “dead” rAAV genomes or promoter-less firefly luciferase followed by the human growth hormone (hGH) pA (kindly provided by J.S.C., University of Washington, Seattle, Washington) were used to generate the control rAAV genomes. The resulting constructs were cotransfected with the pDG6 packaging plasmid into HEK293 cells to developed pressure (LVDevP). Although mdx⁴cv mice treated with µDys appeared to normalize LVDevP, this did not result in a significant increase in RPP. Upon further evaluation of cardiac function, the pressure-volume relationship revealed that systolic pressure response with increased preload was significantly improved with the treatment of either RNR or µDys. However, only RNR treatment resulted in significant improvements in diastolic functional parameters, returning them to values that were similar to wild-type (WT) control hearts. As a further assessment of cardiac function, we tested hearts using a high workload challenge protocol. Both RNR and µDys treatments improved systolic function in mdx⁴cv hearts without compromising cardiac reserve. These positive results suggest that targeted expression of RNR within the myocardium can significantly improve contractile performance in an advanced-age model of DMD cardiomyopathy and may have therapeutic implications for DMD patients.

We have developed a cardiac function-enhancing gene therapy approach that targets myosin in contractile filaments by overexpressing the enzyme ribonucleotide reductase (RNR). RNR converts adenine diphosphate (ADP) to deoxy-ADP (dADP), which is rapidly converted to deoxy-adenosine triphosphate (dATP) in cells. In numerous in vitro studies, we have shown that dATP increases cross-bridge binding and cycling, resulting in stronger, faster contraction and faster relaxation (38-45). We have also reported that dATP improves contractile properties of myocardium from end-stage human heart failure (HF) in vitro (42) and dogs with end-stage idiopathic dilated cardiomyopathy (46). In normal rodent muscle, we reported that increases in cardiomyocytes and cardiac function occur with as little as ~1% of the ATP pool in the dATP form (40,47). Similarly, rAAV-mediated delivery of RNR under cardiac-specific regulatory control resulted in enzyme overexpression exclusively in cardiomyocytes and significantly improved left ventricular function without adverse cardiac remodeling in normal and infarcted rodent hearts (48). Our data indicated that dATP could rescue the preload responsiveness of failing hearts, suggesting restoration of the abnormal Frank-Starling Law of the Heart that often occurs in HF.

In the current study, we compare the relative therapeutic capacity of CK8-driven µDys or cardiac troponin T (cTnT)-driven RNR, via intravenously administered rAAV vectors in an advanced-age, DMD cardiomyopathy mouse model. We show a restoration of myocardial workload as indicated by rate pressure product (RPP) for baseline function in mdx⁴cv mice treated with RNR. This outcome was primarily attributed to the normalization of left ventricular forces.
generate rAAV vectors carrying serotype 6 capsids, which were harvested, enriched, and quantitated as previously described (49).

**VECTOR GENOME QUANTIFICATION.** Total DNA was extracted from flash-frozen tissue samples with TRIzol Reagent (MRC Inc., Cincinnati, Ohio), according to manufacturer’s instructions. All real-time polymerase chain reaction (PCR) reactions were performed on a QuantStudio 3 Real Time PCR System (Applied Biosystems, Foster City, California) in a total volume of 15 µl, consisting of 5 µl sample DNA, 10.0 µl TaqMan Universal PCR Master Mix (Applied Biosystems), 0.2 µM of each primer, and 0.1 µM TaqMan custom probe (Applied Biosystems). Reaction conditions were 50°C for 2 min, 95°C for 10 min, and 40 cycles of 95°C for 15 s followed by 60°C for 1 min. Each sample was analyzed in triplicate for concentration of total murine genomes and of total vector genomes. For vector genome detection by quantitative PCR, the primers used to amplify either the rAAV6-cTnT455-RNR or rAAV6-∆cytomegalovirus(CMV)-Luc (control vector) were unique to each vector. For vector genome quantification by quantitative PCR, the primers used to amplify either the rAAV6-cTnT455-RNR or rAAV6-∆cytomegalovirus(CMV)-Luc (control vector) were unique to each vector. For vector genome quantification by quantitative PCR, the primers used to amplify either the rAAV6-cTnT455-RNR or rAAV6-∆cytomegalovirus(CMV)-Luc (control vector) were unique to each vector.

**TISSUE PROCESSING AND IMAGING ANALYSIS.** Tissues were collected and analyzed 5 months post-administration of vectors with age-matched male control vector (rAAV6-ΔCMV-Luc) injected mdx<sup>4cv</sup> and WT mice. Hearts were either snap frozen in liquid nitrogen or were embedded in optimal cutting temperature compound (VWR International, Bridgeport, New Jersey) and flash frozen in liquid nitrogen cooled isopentane for histochemical or immunofluorescence analysis. The snap frozen samples were further processed by grinding to a powder under liquid nitrogen in a mortar kept on dry ice for subsequent extraction of nucleic acid and protein.

Heart cross-sections (10 µm) were co-stained with antibodies raised against alpha 2-laminin (Sigma, St. Louis, Missouri; rat monoclonal, 1:200), the hinge-1 domain of dystrophin (alexa488 conjugated MANEX1011b, Developmental Studies Hybridoma Bank, University of Iowa, mouse monoclonal, 1:200), the human RRM1 (Abcam, Cambridge, United Kingdom; rabbit monoclonal, 1:200), and the human RRM2 (Abcam, rabbit monoclonal, 1:200). Conjugated secondary antibodies (Jackson Immuno, Goat anti-Rabbit) were used at a 1:500 dilution. Slides were mounted using ProLong Gold with DAPI (Thermo Fisher Scientific) and imaged via a Leica SPV confocal microscope. Confocal micrographs covering a majority of the heart left ventricular muscle sections were acquired and montaged via the Fiji toolset (ImageJ) and InDesign (Adobe, San Jose, California). For histology, Masson’s trichrome staining was used to examine heart cross-sections. Briefly, 10-µm muscle cryosections were sequentially stained in Wiegert’s iron hematoxylin (10 min), 1% Ponceau-acetic acid (5 min), and 1% aniline blue (5 s).

**WESTERN BLOTTING.** Radioimmunoprecipitation analysis buffer supplemented with 5 mM ethylenediaminetetraacetic acid and 3% protease inhibitor cocktail (Sigma, Cat# P8340), was used to extract muscle proteins for 0.5 h on ice with gentle agitation every 10 min. Total protein concentration was determined using Pierce BCA assay kit (Fisher Scientific, Kent, Washington). Muscle lysates from WT, control mdx<sup>cre</sup>, and treated mdx<sup>cre</sup> (30 µg) mice were denatured at 99°C for 10 min, quenched on ice, and separated via gel electrophoresis after loading onto Criterion 4–12% Bis-Tris polyacrylamide gels (BioRad). Overnight protein transfer to 0.45 mm polyvinylidene difluoride membranes was performed at constant 43 volts at 4°C in Towbin’s buffer containing 20% methanol. Blots were blocked for 1 h at room temperature in 5% non-fat dry milk for 1 h before overnight incubation with antibodies raised against the hinge-1 region of dystrophin (Developmental Studies Hybridoma Bank, University of Iowa, 1:300), anti-RRM1 (Abcam, rabbit monoclonal, 1:1,000), anti-RRM2 (Abcam, rabbit monoclonal 1:1,000), and anti-GAPDH (Sigma, Rabbit polyclonal, 1:50,000). Horseradish-peroxidase conjugated secondary antibody staining (1:50,000) was performed for 1 h at room temperature before signal development using Clarity Western ECL substrate (BioRad) and visualization using a Chemidoc MP imaging system (BioRad).

**QUANTIFICATION OF CARDIAC dATP.** Approximately 25 µg of flash frozen, freshly ground ventricle...
cardiac tissue was used for direct quantification of intracellular dATP using the high-performance liquid chromatography (HPLC)-with tandem mass spectrometry (MS/MS) method previously described (50). Briefly, samples were extracted 1 to 3 days before measurement using a 50% methanol solution. The supernatant was stored at -20°C until ready for injection into the HPLC-MS/MS system. A Water’s Xevo-TQ-S mass spectrometer coupled with a Water’s Acquity I-Class HPLC was used for the analysis (Milford, Massachusetts). Monitoring in negative mode via electrospray ionization was used to acquire MS/MS ions. dATP concentrations were quantified with standards and normalized to tissue weight.

LANGENDORFF ISOLATED PERFUSED HEART EXPERIMENTS. Ex vivo cardiac function was assessed in Langendorff isolated heart preparations as previously described (47,48,51). Hearts were perfused at a constant pressure of 80 mm Hg with a modified Krebs-Henseleit buffer supplemented with glucose and pyruvate. The perfusate contained (mmol/l): 118 NaCl, 25 NaHCO3, 5.3 KCl, 2.0 CaCl2, 1.2 MgSO4, 0.5 ethylenediaminetetraacetic acid, 10.0 glucose, and 0.5 pyruvate, equilibrated with 95% O2 and 5% CO2 (pH 7.4). Temperature was maintained at 37.5°C throughout the protocol. Left ventricular (LV) function was monitored via a water-filled balloon inserted into the LV and connected to a pressure transducer. LV systolic pressure (LVSP), end diastolic pressure, heart rate (HR), and minimum and maximum rate of pressure change in the ventricle (±dP/dt) were obtained from the attached data acquisition system (PowerLab, ADInstruments, Colorado Springs, Colorado). After 5 min of stabilization, hearts were equilibrated for 10 min at spontaneous HRs and then fixed at a HR of ~450 beats/min with an electrical stimulator (Grass Technologies, Warwick, Rhode Island). Pressure-volume relationships (i.e., Frank-Starling curves) were assessed by gradually increasing the volume of the LV balloon. After a 5-min recovery period, the perfusate was changed to an identical buffer as above except for the addition of 4.0 mmol/l CaCl2 to simulate a high workload challenge for 20 min.

STATISTICAL ANALYSIS. All values are reported as means ± SEM. Starling curves and high workload function were analyzed by 2-way repeated measures analysis of variance followed by pairwise comparisons using Tukey’s alpha adjustment method. Other endpoint data were analyzed via 1-way analysis of variance or Student’s t-tests as appropriate. Kaplan-Meier methods were used to analyze survival curves and compared using the log-rank test. Statistical significance was tested at the p < 0.05 level. Statistical analyses were completed using Prism 7.0 (GraphPad Software, San Diego, California).

RESULTS

IMPROVEMENTS IN BASELINE CARDIAC FUNCTION IN VECTOR-TREATED MDX4CV HEARTS. As depicted in Figure 1, 22- to 24-month-old mdx4cv mice were administered 1 of 3 treatments: rAAV6-cTnT455- RNR (referred to as mdx4cv+RNR); rAAV6-CKB- μDys (referred to as mdx4cv+μDys), or rAAV6-ΔCMV-Firefly Luciferase control vector (referred to as mdx4cv-ΔLuciferase) at a dose of 2 x 10^14 vg/kg. By the end of the 20-week treatment period, both mdx4cv+RNR and mdx4cv+μDys mice showed improvements in survival rates compared to mdx4cv mice, although this did not reach statistical significance (Supplemental Figure 1). At the end of 5 months, an extensive evaluation of ex vivo cardiac function using the Langendorff isolated heart preparation was performed. The isolated heart technique allows for the direct assessment of inherent myocardial function without the confounding effects of neuro-humoral or other systemic variables. An additional cohort of age-matched, untreated C57BL6 mice (WT) was used as comparison control. At baseline, RPP was significantly decreased in mdx4cv hearts due to an approximate 20% decrease in LVDevP (Supplemental Figures 1A and 1B). RNR-treated mdx4cv mice exhibited a restoration of RPP (p = 0.056) primarily due to a normalization of LVDevP (Supplemental Figures 2A and 2B). Although μDys-treated mdx4cv hearts appeared to normalize LVDevP, this did not lead to a significant improvement in RPP (Supplemental Figures 2A and 2B). Both +dP/dt and -dP/dt, an index of ventricular contractility and relaxation, respectively, were decreased 30% in mdx4cv hearts (p = 0.061). The +dP/dt was similar to control in both RNR-treated mdx4cv and μDys-treated mdx4cv hearts. However, only RNR-treated mdx4cv hearts showed -dP/dt values similar to control levels (Supplemental Figures 2C and 2D).

POSITIVE CHANGES IN FRANK-Starling MECHANICS IN VECTOR-TREATED MDX4CV HEARTS. To evaluate further systolic and diastolic function in vector-treated mdx4cv hearts, we examined the pressure-volume relationship (i.e., Frank-Starling mechanism) in the isolated perfused heart preparation. The LVSP response to increased preload was significantly improved in both in mdx4cv+RNR and mdx4cv+μDys hearts compared to mdx4cv (Figure 2A). However, only RNR treatment improved the diastolic response in mdx4cv hearts, to levels similar to WT (Figure 2B). Both contractility and relaxation (i.e., +dP/dt and
-dP/dt, respectively) were impaired in mdx4cv compared to age-matched control subjects (Figures 2D and 2E). Both mdx4cv+ RNR and mdx4cv+ μDys hearts had significantly elevated +dP/dt values above mdx4cv (Figure 2D). Interestingly, treatment of mdx4cv hearts with RNR also significantly improved -dP/dt values (Figure 2E). All told, these data suggest that both RNR and μDys treatment can improve systolic function in mdx4cv hearts. However, only the RNR treatment corrected diastolic dysfunction in mdx4cv hearts.

AUGMENTED RESPONSE TO INCREASED CARDIAC WORKLOAD IN TREATED MDX4CV HEARTS. We previously reported that RNR overexpression in transgenic or vector-treated mouse hearts elevated baseline function but did not impair the response to a short-term physiologic increase in cardiac work (47,48). To verify that the improved systolic and diastolic function in RNR-treated mdx4cv hearts at baseline was not associated with an inability to respond to an increased energetic demand, we stressed hearts with a combination of high calcium and elevated heart rates, via pacing stimulation. As shown in Figures 3A and 3B, mdx4cv hearts had a blunted response to the increased workload as both LVDevP and RPP were ~25% to 30% lower than WT hearts. In addition, both +dP/dt and -dP/dt were impaired in mdx4cv relative to WT hearts (Figures 3C and 3D). Systolic parameters in mdx4cv+μDys hearts were effectively improved and similar to age-matched WT hearts for the entire duration of the workload challenge.
Measures of systolic function significantly increased in mdx<sup>4cv</sup> RNR hearts during the initial half of the high workload protocol and remained ~15% higher than mdx<sup>4cv</sup> (Figures 3A to 3C). Interestingly, -dP/dt values tended to be elevated only in mdx<sup>4cv</sup> RNR hearts during the physiologic challenge (Figure 3D). These data show that both RNR and μDys treatments improve systolic function in mdx<sup>4cv</sup> hearts without compromising cardiac reserve. Combined with the baseline and pressure-volume relationship assessments, our data show that, in addition to the systolic enhancements, RNR has an added benefit of improving diastolic function.

**RNR AND μDys TRANSDUCTION, EXPRESSION, AND CARDIOMYOCYTE LOCALIZATION.** To evaluate the localization of RNR and μDys protein within the hearts of mice, we performed immunofluorescence imaging. As shown in Figure 4, the RNR subunit (Rrm1) was robustly expressed in ventricles of RNR-treated mice. The expression of μDys appeared to be saturated relative to full-length dystrophin levels, with both being properly localized to the sarcolemma of cardiomyocytes. We also evaluated general muscle histopathology and potential differences in myocardial fibrosis by Masson trichrome staining, and observed no discernable difference between treated or untreated mdx<sup>4cv</sup> mice (Figure 5). In addition, neither RNR nor μDys treatment significantly altered body weight, heart weight, or the heart weight-to-body weight ratio (Supplemental Figure 3). Western blotting was performed to determine the extent of rAAV vector 6-mediated RNR and μDys protein expression profiles in ventricular tissue (Figure 6). We observed μDys protein expression in ventricular tissue that approached levels similar to WT mice, whereas both human RNR subunits were found to be elevated to comparable levels within ventricular tissue (Figure 6A). To evaluate the relative proportions of
dATP concentrations within ventricular tissue, we performed HPLC-MS/MS analysis on ground ventricular tissue from mdx<sup>4cv</sup> and mdx<sup>4cv</sup>+ RNR mice. The concentration of dATP within the ventricular tissue obtained from mdx<sup>4cv</sup> mice treated with RNR (0.57 ± 0.22 pmol dATP/mg) was approximately 10-fold higher relative to mdx<sup>4cv</sup> control subjects (0.05 ± 0.02 pmol dATP/mg) (Figure 6B). For adult WT, we previously reported an average dATP value of 0.02 pmol/mg tissue with a SD of 0.01 (50). Additionally, cardiac vector genome data was comparable relative to the vector dose administered (Figure 6C).

**DISCUSSION**

In the present study, we used a novel gene therapy approach that targets myosin in the contractile filaments of cardiomyocytes via overexpression of the RNR enzyme to rescue cardiomyopathy in a DMD mouse model. RNR overexpression results in elevated dATP, which can be used by cardiac myosin (in place of ATP), and increases cross-bridge binding and cycling, resulting in stronger, faster contraction and faster relaxation (38–45,52). We developed an rAAV vector that over-expresses RNR selectively in heart...
muscle via inclusion of a modified cardiac-specific enhancer/promoter derived from the human cTnT gene, which facilitates increases in myocyte contraction and cardiac performance in normal rodent hearts as well as in infarcted rodents and pig hearts (48,53). Importantly, we previously showed that dATP-producing cells deliver it to surrounding myocardium by diffusion through gap junctions (54), such that only a minority of cardiomyocytes needs to be transduced to have global benefits within the heart. We now show that using this vector technology leads to a clear benefit of improving cardiac function in an advanced-age model of DMD cardiomyopathy.

Early manifestations of impaired cardiac dysfunction in mdx mice are generally not reported. Khairallah et al. (55) observed a decline in LV function in isolated perfused hearts that coincided with decreased fatty acid oxidation and increased glucose oxidation. However, perfused heart function in mdx mice was maintained at 8 months, despite significant reductions in phosphocreatine levels and free energy availability from ATP hydrolysis (56). The authors surmised that young adult mdx hearts, akin to DMD patient hearts, experience right ventricular dilation, LV diastolic deficits, and abnormal energy metabolism. More recently, a declination in cardiac function was not observed until 12 months of age (57) and abnormal in vivo pressure-volume dynamics were observed in 22-month-old mdx mice (58). Treatment of young male mdx mice with rAAV6 vector delivering cytomegalovirus (CMV) promoter/enhancer driven microdystrophin did not correct the impairments in +dP/dt, −dP/dt, or LV systolic pressure when assessed at 5 months of age via hemodynamic analysis (35). However, an improvement was noted for the preload recruited stroke work in mdx mice treated with μDys compared to untreated mdx or WT control subjects (35).

In our current study, 27-month to 29-month-old mice were subjected to ex vivo assessment of cardiac function using the Langendorff isolated heart preparation, which is a century-old methodology with several advantages and limitations (59). The perfusate used is similar to, but not the same as blood, and situations of physiologic challenge (e.g., Frank-Starling and high calcium) may exaggerate the in vivo situation. However, the procedure remains a simple and reproducible experiment that allows for interrogation of cardiac physiology in the absence of confounding systemic variables and serves as a viable

---

**FIGURE 4** Cardiac Transduction Following Intravenous Delivery of Ribonucleotide Reductase or Microdystrophin

At 5 months after vector administration, cryosections were prepared and immunostained with antisera against dystrophin or ribonucleotide reductase. A considerable level of protein is detected for each ribonucleotide reductase subunit-1 (human specific) as indicated by immunofluorescent staining (red) localized primarily within the cytoplasm of cardiomyocytes with occasional perinuclear accumulation (upper panel). On the lower panel, the robust level of expression for dystrophin in WT and in aged mdx4cv mice treated with AAV6-CK8-μDys (laminin staining, inset image). Abbreviations as in Figures 1 and 2.
tool to perform cardiac phenotyping in preclinical studies (60). Under baseline conditions and at spontaneous heart rates, we observed a significant reduction in RPP in mdx<sup>4cv</sup> hearts. Decreased systolic and diastolic performance in mdx<sup>4cv</sup> hearts also existed while examining the length-tension relationship (i.e., Frank-Starling mechanism). Treatment of mdx<sup>4cv</sup> mice with either the RNR or the μDys vector restored systolic pressure development without affecting spontaneous HRs at baseline. Both of the treatments restored the disrupted Frank-Starling response, particularly for systolic function. The RNR treatment also had beneficial effects on the diastolic properties of the mdx<sup>4cv</sup> myocardium. This strongly supports our previous studies where we observed a tendency for overexpression of RNR to improve myocardial diastolic response in young, healthy, transgenic mice (47), mice treated with AAV (48), and in a porcine HF model (53).

In addition to the evaluation of basal cardiac performance, we tested cardiac reserve with a combination of high calcium plus elevated HRs and confirmed a significantly blunted response in 27-month to 29-month-old mdx<sup>4cv</sup> hearts. Consistent with a previous report in young mdx mice (35), expressing μDys in aged mdx<sup>4cv</sup> hearts significantly improved systolic performance during increased physiologic demand to a level similar to age-matched healthy control subjects. We previously reported that transgenic or vector-directed overexpression of RNR did not impair cardiac reserve during increased physiologic demand in young healthy hearts (47,48). Herein, we report that RNR over-expression in mdx<sup>4cv</sup> hearts normalizes both the systolic and diastolic response to an increased cardiac challenge.

Approximately two-thirds of DMD mutations are deletions that span 1 or more exons, often leading to large deletions clustering around 2 mutational...
hotspots; the most common spanning from exons 45-55 resulting in removal of a central portion of the rod domain inclusive of disrupting the neuronal nitric oxide synthase (nNOS) localization domain. The second most common hotspot spans from exons 3-19, and removes the majority of the amino-terminal actin-binding domain 1 which is essential for dystrophin function. When such deletions interrupt the reading frame, the resultant mutated protein usually expresses at extremely low levels and associates with the loss of ambulation at or before 12 years of age. Even when such deletions produce an in-frame partially functional truncated protein, such as occurs in BMD, dramatic phenotype diversity can occur. For example, in a previous study, BMD subjects whose out-of-phase deletions, toward the alignment of adjoining spectrin-like repeats, developed dilated cardiomyopathy at nearly a decade earlier than in patients with in-phase deletions (61).

In contrast to large deletion mutations, there are reported cases where individual missense mutations lead to X-linked dilated cardiomyopathy at nearly a decade earlier than in patients with in-phase deletions (61). In one case, a novel missense mutation within exon 9 at nucleotide 1043 resulted in a T279A amino acid change in a highly conserved position of mutation. This mutation resulted in a substitution of a beta-sheet for alpha-helical structure, destabilizing the protein, and leading to the cardiac specific phenotype described by the authors (63).

DMD-related cardiomyopathy usually occurs during middle to late adolescence, but the clinical presentation is deceptive, as patients are wheelchair-bound and are not required to perform increased cardiac workload. The diversity of cardiac phenotype in DMD suggests many levels of pathogenic mechanisms. The pathologic heterogeneity of the DMD ventricular myocardium is a consequential result of myocardial atrophy (65,66), compensatory mechanisms leading to cardiac remodeling with ensuing ventricular dilation and fibrosis (67,68). Absence of clear genotype-phenotype correlation in DMD probably results from at least 4 secondary cellular processes including aberrant intracellular Ca$^{2+}$ homeostasis, decreased nitric oxide-cyclic guanosine monophosphate pathways, mitochondrial dysfunction, and increased reactive oxygen species, which individually or collectively influence the clinical phenotype (69). As an indication of the progressive nature of DMD cardiomyopathy, the estimated overall incidence of latent DCM is 25% by 6 years of age and 59% by 10 years of age in DMD patients (70). As such, further evidence suggests latency in cardiac dysfunction at basal levels that becomes more pronounced with an induction of increased physiological demand. Consistent with these observations, an impaired response to beta-adrenergic stimulation by either dobutamine or isoproterenol can be detected in mdx mice at 3 to 4 months of age (35,71). Exercise can
potentially be a double-edged sword for DMD, where the enthusiasm for potential skeletal muscle benefits can be dampened by the insidious cardiotoxicity from training (72-74). With gene replacement therapy via rAAV-mediated μDys in current ongoing clinical trials, it will be of interest to assess cardiac function to determine whether additional therapeutic support in the form of increased contractility will be beneficial. Relative expression assays by immunofluorescence and Western blotting indicate robust expression levels for the RNR subunits (RRM1 and RRM2) and μDys in the vast majority of cardiomyocytes. However, intracellular variability in RNR protein detection (via immunostaining) was observed for both RRM1 and RRM2, indicating that not all cardiomyocytes were effectively transduced. Nevertheless, we previously have shown that gap junction transport of dATP from transduced cardiomyocytes to adjacent cardiomyocytes occurs (54), which likely accounted for the consistently elevated LV function of mice treated with the rAAV vector that over-expresses RNR. This is in contrast to the anchored sarcolemma localization of μDys, which would occur only in transduced muscle cells. Additionally, because muscle-specific regulatory cassettes were used for expression of therapeutic proteins, we can surmise that <1% of protein expression would be generated from non-muscle cell types present in the heart, suggesting that the functional benefit was truly caused by cardiomyocyte transduction. As previously stated, the cTnT regulatory cassette drives RNR expression only in heart muscle, whereas the CK8 regulatory cassette drives μDys expression no selectively in both cardiac and skeletal muscle cells, but at only very low background levels in other tissues. This raises the possibility that the functional benefit of expressing μDys in skeletal muscles might increase energetic demands on the heart, thereby partially masking some of the μDys-derived cardiac functional benefits (37). Because RNR delivery to DMD mice of advanced age increased cardiac function in the absence of RNR expression in skeletal muscle, and because over-expression of endogenous RNR should be nonimmunogenic, supplemental RNR therapy in conjunction with μDys therapy might be beneficial for DMD patients. Future studies are aimed at determining the extent of functional restoration by combining both RNR- and μDys-based therapies.

ACKNOWLEDGMENTS The authors thank James Allen and Christine Halbert (Wellstone Muscular Dystrophy Specialized Research Center, University of Washington, Seattle, Washington) for assistance with vector production, purification, and quality assessment.

PERSPECTIVES

COMPETENCY IN MEDICAL KNOWLEDGE: RNR over-expression represents an emerging therapy for improving cardiac dysfunction via cardiac myosin activation in a variety of clinical situations. Currently, there are 3 ongoing clinical trials using rAAV-mediated variants of μDys that have shown broad promise in terms of safety, and in biomarker indicators suggesting pathologic improvements. If cardiac dysfunction is detected in the patients from these clinical studies, our studies in aged, mdx mice suggest that combinatorial RNR therapy may be beneficial.

TRANSLATIONAL OUTLOOK: Our novel strategy of vector-mediated, cardiac-specific over-expression of RNR shows promising potential for rescuing both systolic and diastolic function in aged, DMD mice even in the absence of addressing the underlying dystrophin deficiency. Future studies investigating the combined effects of μDys and RNR may disclose an improved therapeutic strategy to provide structural and functional improvement of DMD patient hearts.
