1. Computational Details

Table 1 provides ranges of the regular grids used for the electronic $\rho_{\text{el}}$ nuclear $\rho_{\text{nuc}}$ densities.

2. Nuclear dynamics

The potential energy curves, Figure 1, within each group of molecules, i.e. one group is ethane, ethene and ethine, show force constants increasing with bond order. Bonds of the same order show force constants decreasing with increasing reduced mass. Thus, the periods of the vibrations increase upon exchanging C by Si and by lowering the bond order. Figure 1 shows snapshots of the corresponding nuclear wave packets at $t = 0$ fs and when the inner turning points are reached at $t = t_{tp}$ for the first time. To compare the electronic rearrangement in the different bonds, we select the initial nuclear states such, that the amplitude $A = \langle \zeta \rangle (0) - \langle \zeta \rangle (t_{tp})$ reached within the first vibrational period equals 0.5 \text{\AA} for each system. A comparison of such an equal amplitude scenario to an equal energy scenario for the H_nCCH_n molecules was made in Ref. [1]. The key figures, such as excitation energies with respect to the nuclear ground states, mean bond lengths and vibrational periods of the nuclear quantum dynamics are given in Table 2.

Figure 1. Potential energy curves from MRCI/cc-pVTZ calculations for the a) organosilicon b) hydrocarbon and c) hydrosilicon model vibrations. Overlaid are two snapshots of nuclear wave packets for each molecule. The wave packets denoted by full lines represent the initial nuclear density while ones denoted by dashed lines show the nuclear density at $t = t_p$ when the inner turning point is reached for the first time. The heights of the baselines of the wave packet pairs represent the mean total energy $\bar{E}$ of the respective vibration. All wave packets are scaled equally.
