Two-Dimensional Diffusion in the Presence of Topological Disorder

Ligang Chen and Michael W. Deem
Department of Physics & Astronomy
Rice University, Houston, TX 77005-1892

How topological defects affect the dynamics of particles hopping between lattice sites of a distorted, two-dimensional crystal is addressed. Perturbation theory and numerical simulations show that weak, short-ranged topological disorder leads to a finite reduction of the diffusion coefficient. Renormalization group theory and numerical simulations suggest that longer-ranged disorder, such as that from randomly placed dislocations or random disclinations with no net disclinicity, leads to subdiffusion at long times.

I. INTRODUCTION

Diffusion in random media is a well-studied problem [1]. The mean-square displacement of a tracer particle behaves at long times in a way that depends on the character of the random forces induced on the tracer by the disorder. Forces that arise from random potentials lead to a reduction of the transport, with subdiffusion possible for diffusion of an ion in a medium with quenched charges obeying bulk charge neutrality [1]. Interestingly, the same subdiffusion results from diffusion of an ion in a medium with randomly-placed, quenched dipoles [2, 3, 4, 5]. Forces that arise from entrainment along fluid streamlines lead to an increase in the transport, with the well-known result of turbulent super-diffusion possible for random streamlines with statistics characteristic of fluid turbulence [1].

Distortion of the underlying lattice upon which the diffusion occurs is a very different type of disorder. In particular, topological defects such as dislocations or disclinations should affect the transport properties of a diffusing tracer particle. These topological defects cause a global rearrangement of the connectivity of the lattice upon which the diffusion occurs. Moreover, there is an elastic response of the lattice to such defects, and so there is also local expansion or compression of the crystal unit cells. Study of how such topological defects affect the transport is, therefore, an interesting and challenging problem. Among other results, it might be expected that randomly-placed dislocations and random disclinations with no bulk disclinity will lead to similar dynamics, given the results regarding dynamics in random potentials and the analogy between linear elasticity theory and electrostatics.

Transport in a two-dimensional crystal with topological defects, then, remains an interesting and unsolved problem. Our model of surface diffusion, and the Fokker-Planck equation that results, is introduced in Sec. II. How the topological defects affect the transport, and a field theoretic description used to analyze the dynamics, is described in Sec. III. Perturbation theory and computer simulation are used to examine the effect of non-singular topological disorder on the diffusion coefficient in Sec. IV. The possibility of anomalous diffusion in singular topological disorder is examined by renormalization group theory and computer simulation in Sec. V. A discussion of the results, and their relation to the previous literature, is given in Sec. VI. A discussion of the effects of torsion, which exists solely within the cores of defects, is given in Sec. VII. We conclude in Sec. VIII.

II. THE SURFACE DIFFUSION MODEL

We consider a particle hopping on the surface of a crystal. The particle hops only between nearest-neighbor lattice sites, and the rate of hopping is constant. In particular, since surface diffusion is usually an activated process, the rate to hop between neighboring sites is assumed to be independent of the distance between sites. Disorder in the spatial arrangement of the surface lattice sites indirectly affects the diffusion dynamics through modification of the hopping events.

We derive the Fokker-Planck, or diffusion, equation for the surface species by two independent methods. In the first method, the hopping dynamics is derived from a physically-motivated consideration of the master equation for the process. In the second method, the result is derived in an efficient fashion by considering a change of variables in the field theory for the dynamics.

The particle is considered to hop on an irregular grid of lattice sites. The probability for particles to be on a given site, \( P(\mathbf{r}) \), decreases with time due to hopping of particles off the site and increases with time due to hopping of neighboring particles onto the site (see Figure 1).
The general expression for diffusion in curved space is

\[ g^{ij} = \frac{\partial r_i}{\partial \sigma^a} \frac{\partial r_j}{\partial \sigma^a} \] \tag{5} \]

will be used. The shorthand \( \partial_i = \partial / \partial r_i \) will also be used. Equation (4) is a relation for the probability distribution in \( r \) space. The relation for the probability distribution in \( \sigma \) space requires a Jacobian:

\[ P(r, t) = G(\sigma, t) \frac{\partial}{\partial r_i} \ln \det \frac{\partial \sigma}{\partial r_i} \] \tag{6} \]

The Jacobian is given by

\[ \frac{\partial}{\partial r_i} \ln \det \frac{\partial \sigma}{\partial r_i} = \sqrt{g}(r) \left[ \frac{\partial \sigma_x}{\partial r_x} \frac{\partial \sigma_y}{\partial r_y} - \frac{\partial \sigma_x}{\partial r_y} \frac{\partial \sigma_y}{\partial r_x} \right] \] \tag{7} \]

As noted, the Jacobian is \( \sqrt{g} = (\det g^{ij})^{1/2} = 1/\det g^{ij}^{1/2} \), where the inverse of the matrix \( g^{ij} \) is given by

\[ g_{ij} = \frac{\partial \sigma^a}{\partial r_i} \frac{\partial \sigma^a}{\partial r_j} \] \tag{8} \]

The volume of each unit cell is given by \( V(r) = h^2 / \sqrt{g}(r) \). By detailed balance, since the rates to hop forward and back between any two sites on the crystal are the same, the long-time average number of particles per site must be equal at all sites: \( \lim_{t \to \infty} G(\sigma, t) = \text{const.} \) This implies \( \lim_{t \to \infty} P(r, t) \propto \sqrt{g}(r) \).

Since

\[ \partial_i g^{ij} = \frac{\partial}{\partial r_i} \left( \frac{\partial r_j}{\partial \sigma^a} \frac{\partial \sigma^a}{\partial r_i} \right) = \frac{\partial r_j}{\partial \sigma^a} \frac{\partial \sigma^a}{\partial r_i} + \frac{\partial r_i}{\partial \sigma^a} \frac{\partial \sigma^a}{\partial r_j} = \frac{\partial^2 r_j}{\partial \sigma^a \partial \sigma_j} + \frac{\partial^2 r_i}{\partial \sigma^a \partial \sigma_i}, \] \tag{9} \]

eq. (4) becomes

\[ \frac{\partial G}{\partial t} = D_0 \left( \partial_i g^{ij} - \frac{\partial r_j}{\partial \sigma^a} \frac{\partial r_i}{\partial \sigma^a} \right) \partial_j G + D_0 g^{ij} \partial_i \partial_j G. \] \tag{10} \]

Finally, given that

\[ \frac{1}{\sqrt{g}} g^{ij} \partial_i \sqrt{g} = \frac{1}{2} g^{ij} \partial_i \ln \det g^{-1} \]

\[ = \frac{1}{2} \frac{\partial r_j}{\partial \sigma^a} \frac{\partial r_i}{\partial \sigma^a} \partial_i \ln \det g^{-1} \]

\[ = \frac{1}{2} \frac{\partial r_i}{\partial \sigma^a} \partial_i \ln \det g^{-1}, \] \tag{11} \]

and

\[ \frac{1}{2} \frac{\partial \ln \det g^{-1}}{\partial \sigma^a} = \frac{1}{2} g^{ij} \frac{\partial g^{ij}}{\partial \sigma^a} \]
Laplace-Beltrami operator \[11\] replacing the Laplacian of usual diffusion equation in curved space, with the familiar of topological defects, because it has been assumed in the This equation applies everywhere except within the cores the final expression of the diffusion equation becomes torsion \[9\]. We reevaluate the term \(\frac{\partial^2}{\partial r_i \partial r_j} \ln \det g\partial r_i\) (see below)

\[
\frac{\partial}{\partial r_i} g^\alpha_\beta \partial r_i \partial r_j \partial r_k \sigma_a \partial r_i \partial r_j \partial r_k
\]

the final expression of the diffusion equation becomes

\[
\frac{\partial G}{\partial t} = \frac{1}{\sqrt{g}} \partial_t (\sqrt{g} D_0 g^{ij} \partial_j G) - 2D_0 g^{ij} T^k_{ik} \partial_j G .
\] (18)

Equation (18) is equal to the general expression for diffusion in curved space \[4\]. The difference between the exact answer, eq. (18), and that assuming that the order of differentiation commutes, eq. (13), is given by the torsion term. The torsion is an explicit measure of the non-commutativity of differentiation and is, therefore, a measure of the defect density \[10\]. The diffusion equation does not apply within the cores of defects, where the metric tensor is undefined, and the only place where the torsion is non-zero. The effects of the torsion should probably be studied with a detailed model rather than with the long-wavelength, continuum theory of the diffusion equation. For this reason, we exclude this torsion term (although see section VII below). The long range, external to defect core, effects of the topological defects are, of course, included in eq. (13) through the metric tensor \(g^{ij}\) and \(\sqrt{g}\). Refs. \[5\] included the torsion term explicitly, and a series of approximations allowed the generation of non-physical dynamics.

Equation (13) can, alternatively, be derived by consideration of the field-theoretic representation of the diffusion operator \[12\]. In this representation, the Green function is given by an average over a field:

\[
G(r, t) = \langle a(r, t) \rangle ,
\] (19)

where the average is taken with respect to the weight \(\exp(-S)\). The particle hopping occurs in \(\sigma\) space without regard to the distortion of the crystal, as the rate of hopping is independent of the distance between lattice sites. The action for such normal diffusion is given by

\[
S = \int_0^\infty dt \int d\sigma \left\{ \tilde{a} [\partial_t + \delta(t)] a - D_0 \partial^2 a \right\} + \int d\sigma n_o(\sigma) \tilde{a}(r, 0) ,
\] (20)

where \(n_0\) is the initial density profile, and details of the replica indices used to accommodate averaging over disorder have been suppressed \[10\]. This action is enclosed in quotations since the \(\sigma\) space is not well-defined in the presence of topological defects. That the diffusion is normal in \(\sigma\) space, however, does make it clear that the limiting distribution should be \(\lim_{t \to \infty} G(\sigma, t) = (\text{const})\). From eq. (6), then, the limiting distribution in \(r\) space is given by \(\lim_{t \to \infty} P(r, t) = (\text{const}) \sqrt{g}(r) = \sqrt{g}(r)/\int d\sigma \sqrt{g}(r) \). While this result may be surprising, note that the defects which distort the geometry must affect the limiting distribution, unlike the typical case in differential geometry where the observables are described by a theory independent of the coordinate system. This explicit result for the limiting distribution agrees with the prediction from the simple detailed balance argument given above. Note that \(\int d\sigma \sqrt{g}(r)\) is a
constant for a given realization of the quenched disorder. The long-time normalization factor for the probability is fixed to be the inverse of this integral by the initial condition \( P(r,0) = \delta(r) \). Equation 13 for the dynamics conserves \( \int dr \sqrt{g(r)} G(r,t) \), hence, the probability distribution, \( P(r,t) = \sqrt{g(r)} G(r,t) \), remains normalized to unity for all times \( t \geq 0 \). After change of variables from \( \sigma \) to \( r \), again making the assumption of being outside defect cores so that differentiation commutes, the action becomes

\[
S = \int_0^\infty dt \int dr \left\{ \sqrt{g} \hat{a} \partial_t \phi - \hat{a} \partial_t \left[ \sqrt{g D_0} g^{ij} \partial_i \phi \right] \right\} + \int dr \sqrt{g} \mu_0(r) \hat{a}(r,0) .
\]

Finally, integrating out the \( \hat{a} \) field, using eq. 19, and noting that for the Green function \( n_0(\sigma) = \delta(\sigma) \), the Fokker-Planck equation is

\[
\frac{\partial G}{\partial t} = \frac{1}{\sqrt{g}} \partial_i (\sqrt{g D_0} g^{ij} \partial_j G) ,
\]

with \( G(r,0) = \delta(r)/\sqrt{g(r)} \). The field-theoretic result, eq. 22, is the same as that derived by more physically-motivated means, eq. 13.

### III. The Model of Topological Disorder

The topological defects modify the diffusive motion of the particle by affecting the \( g^{ij} \) in the Fokker-Planck equation. Once \( g^{ij} \) is determined, eqs. 13 and 15 provide the means to calculate the transport properties. It is conventional in continuum elasticity theory to relate the spatial coordinates to the lattice coordinates by

\[
r(\sigma) = \sigma + u(r) ,
\]

where the displacement field \( u \) is written in terms of the \( r \) variables that remain well-defined even in the presence of topological defects. The \( \sigma \) space, on the other hand, does not remain well-defined, since the effect of dislocations is to add or remove wedges of lattice sites from \( \sigma \) space, and the effect of dislocations is to add or remove half-lines of lattice sites from \( \sigma \) space. For a dislocation at the origin with Burgers vector \( b \), the displacement fields are given by

\[
2\pi u_i^{\text{disloc}} = -\frac{\mu + \lambda}{2(\mu + \lambda)} \frac{\epsilon_{kl} b^l r^k r_k}{r^2} + b_i \tan^{-1} \frac{r_y}{r_x} - \frac{\mu}{2\mu + \lambda} \epsilon_{i1} b_1 \ln \frac{r}{h} ,
\]

where \( \mu \) and \( \lambda \) are the two-dimensional Lamé coefficients, \( \epsilon_{11} = \epsilon_{22} = 0 \), and \( \epsilon_{12} = -\epsilon_{21} = 1 \). Similarly, for a disclination of strength \( s \) at the origin, the displacement fields are given by

\[
2\pi u_i^{\text{discl}} = -\frac{\mu + \lambda}{2(\mu + \lambda)} \frac{s \epsilon_{ik} r^k r_k}{r_x} \tan^{-1} \frac{r_y}{r_x} + \frac{\mu}{2\mu + \lambda} s \epsilon_{i1} r_1 \ln \frac{r}{h} .
\]

Equation 24 differs from the simplified distortion field used in 6 by the inclusion of the strain field representing the local lattice contraction and expansion. These are the terms in eq. 25 that depend on the Lamé coefficients. Since linear elasticity theory is used, the dislocation field is given by the dipole limit of two superimposed disclination fields:

\[
u_i^{\text{disloc}} = (b_i/s) \epsilon_{ij} \partial_j u_i^{\text{discl}} + \text{const} .
\]

The derivatives of the displacement fields are required to evaluate \( g^{ij} \) from eq. 15. The dislocation fields are preferable for this calculation, as they lead to well-defined Fourier transforms:

\[
\partial_x u_x^{\text{disloc}} = \left[ \frac{\mu + \lambda}{2\mu + \lambda} \frac{2k_x^2 k_y - k_x^2 k_y}{k^4} \right] \hat{b}_x(k) + \left[ \frac{\mu + \lambda}{2\mu + \lambda} \frac{k_x \left( -k_x^2 + k_y^2 \right)}{k^4} + \frac{\mu}{2\mu + \lambda} \frac{k_x}{k^2} \right] \hat{b}_y(k)
\]

\[
\partial_y u_x^{\text{disloc}} = \left[ \frac{\mu + \lambda}{2\mu + \lambda} \frac{2k_x^2 k_y + k_x^2}{k^4} \right] \hat{b}_x(k) + \left[ \frac{\mu + \lambda}{2\mu + \lambda} \frac{k_y \left( -k_x^2 + k_y^2 \right)}{k^4} + \frac{\mu}{2\mu + \lambda} \frac{k_y}{k^2} \right] \hat{b}_y(k)
\]

\[
\partial_x u_y^{\text{disloc}} = \left[ \frac{\mu + \lambda}{2\mu + \lambda} \frac{2k_x^2 k_y - k_x^2 k_y}{k^4} \right] \hat{b}_x(k) + \left[ \frac{\mu + \lambda}{2\mu + \lambda} \frac{k_y \left( -k_x^2 + k_y^2 \right)}{k^4} - \frac{\mu}{2\mu + \lambda} \frac{k_y}{k^2} \right] \hat{b}_y(k)
\]

\[
\partial_y u_y^{\text{disloc}} = \left[ \frac{\mu + \lambda}{2\mu + \lambda} \frac{2k_x^2 k_y + k_x^2}{k^4} \right] \hat{b}_x(k) + \left[ \frac{\mu + \lambda}{2\mu + \lambda} \frac{k_x \left( -k_x^2 + k_y^2 \right)}{k^4} + \frac{\mu}{2\mu + \lambda} \frac{k_x}{k^2} \right] \hat{b}_y(k) .
\]

Note that the \( x \) and \( y \) derivatives of the strain fields are not simply related by the ratio \( k_x/k_y \), due to the presence of the defects. The linearity of elasticity theory has been used to accommodate a density field of defects with Burgers vectors given by \( b(r) \).

The dislocations are assumed to be distributed randomly in the material with correlation function

\[
\left\langle \hat{b}_i(k_1) \hat{b}_j(k_2) \right\rangle = \delta_{ij} (2\pi)^2 \delta(k_1 + k_2) \hat{\chi}(k_1 + k_2) ,
\]

where

\[
\hat{\chi}(k) = \gamma k^\alpha \exp(-\beta k^2) .
\]
Physically, we expect this model of dislocations should generate identical dynamics to one in which disclinations are randomly distributed with correlation function

\[ \langle \hat{s}(k_1)\hat{s}(k_2) \rangle = (2\pi)^2 \delta(k_1 + k_2) \|k_1 + k_2\|^2 \chi(k_1 + k_2). \] (30)

This physical expectation is a mathematical consequence of eq. (24).

With these results in hand, we are now in a position to calculate the action for the field theoretic description of the Green function. The terms in eq. (21) are expressed to linear and quadratic order in \( u_{\text{disloc}} \), and then an average over the random distribution of dislocations is taken. In fact, since eq. (14) is preferable to eq. (15), the theory is written in terms of the fields \( \bar{u}, \bar{c} \), where \( c = \sqrt{\gamma} u \), and \( P = \langle \bar{c} \rangle \). The action is

\[
S = \int_0^\infty dt \int d\bar{r} [\partial_t - (D_0 + \delta D_{II}) \nabla^2 + \delta(t)]c \\
+ \int d\bar{r} \delta(\bar{r})\bar{a}(\bar{r},0) + S_I,
\] (31)

where

\[
S_I = -2D^2 \int dt_1 dt_2 \int_{k_1,k_2,k_3,k_4} \times (2\pi)^2 \delta(k_1 + k_2 + k_3 + k_4) \\
\times \hat{\chi}(k_1,t_1)\hat{e}(k_2,t_1)\hat{a}(k_3,t_2)\hat{c}(k_4,t_2) \\
\times \frac{\mu + \lambda_2 k_1^2 + 2\mu + \lambda_2 k_2^2}{2(2\mu + \lambda_2)} \\
\times \frac{\mu + \lambda_2 k_3^2 + 2\mu + \lambda_2 k_4^2}{2(2\mu + \lambda_2)},
\] (32)

where the notation \( \int_k \) stands for \( \int d^2k/(2\pi)^2 \). The term resulting from a non-zero average of \( u_{\text{disloc}} \) is

\[
\delta D_{II} = \frac{\gamma D_0 \Gamma(n/2)}{2\pi} \left[ \frac{13\lambda^2 + 16\nu\lambda + 25\mu^2}{9(2\mu + \lambda)^2} \right] \\
\times \int_0^\infty dt \int d\bar{r} \chi(\bar{r}) \phi(\bar{r},0) \\
= \frac{\gamma D_0 \Gamma(n/2)}{2\pi} \left[ \frac{13\lambda^2 + 16\nu\lambda + 25\mu^2}{9(2\mu + \lambda)^2} \right].
\] (33)

Exactly the same theory is generated if the correlation function eq. (30) is used with the disclination displacements given by eq. (20).

IV. TOPOLOGICAL DISORDER REDUCES THE DIFFUSION CONSTANT

For the model with \( n > 0 \), the topological disorder reduces the diffusion coefficient by a finite amount. The finite contribution of \( \delta D_{II} \) is explicit in eq. (33). Moreover, standard power counting arguments [17] show that non-perturbative, renormalization effects can be expected from eq. (32) only for \( n \leq 0 \). From perturbation theory on eq. (32) for \( n > 0 \), the contribution to the diffusion coefficient is found to be

\[
\delta D_I = -\frac{\gamma D_0 \Gamma(n/2)}{2\pi} \left[ \frac{4\mu^2 + 2(\mu + \lambda)^2}{(2\mu + \lambda)^2} \right].
\] (34)

The total contribution to the diffusion coefficient is, therefore,

\[
\delta D = \frac{\gamma D_0 \Gamma(n/2)}{2\pi} \left[ \frac{20\mu^2 + 20\mu\lambda + 5\lambda^2}{9(2\mu + \lambda)^2} \right].
\] (35)

To demonstrate the behavior of this model, we perform numerical simulations. The dislocation density fields are constructed with correlation function eq. (28) for \( n = 2 \) using the method of ref. [18]. Equation (27) and an inverse fast Fourier transform are used to calculate the displacement fields in real space. The matrix \( g^{ij} \) is calculated as the inverse of the matrix \( g_{ij} \) given by eq. (3), and the relation \( \sigma = \bar{r} - \bar{u}(\bar{r}) \) is used.

The Fokker-Planck equation, eq. (13), can be considered to result from many small hops, the net effect of which is Gaussian, diffusive motion. So that a hopping process on a lattice reproduces this differential equation, the average and mean-square displacements must be correct at each lattice site. Interestingly, this differential equation can be evaluated by Monte Carlo methods on a perfect, square lattice, even though the differential equation itself describes the motion of a particle in a distorted geometry. To first order in the time step, the mean displacement is given by

\[
\langle \hat{r}_i(\Delta t) \rangle = \int d\bar{r} \sqrt{\gamma} \hat{r}_i G(\bar{r},\Delta t) \\
= \int_0^{\Delta t} dt \int d\bar{r} \sqrt{\gamma} \hat{r}_i \partial_t G(\bar{r},t) \\
+ \int d\bar{r} \sqrt{\gamma} \hat{r}_i G(\bar{r},0) \\
= \frac{D_0 \Delta t}{\sqrt{\gamma}} \partial_j (\sqrt{\gamma} g^{ij}),
\] (36)

where eq. (33) and integration by parts twice has been used in the last step. Similarly, to first order, the mean-square displacement is given by

\[
\langle \hat{r}_i(\Delta t) \hat{r}_j(\Delta t) \rangle = \int d\bar{r} \sqrt{\gamma} \hat{r}_i \hat{r}_j G(\bar{r},\Delta t) \\
= \int_0^{\Delta t} dt \int d\bar{r} \sqrt{\gamma} \hat{r}_i \hat{r}_j \partial_t G(\bar{r},t) \\
+ \int d\bar{r} \sqrt{\gamma} \hat{r}_i \hat{r}_j G(\bar{r},0) \\
= 2D_0 \Delta t \delta g^{ij},
\] (37)

where eq. (13) and integration by parts twice has again been used in the last step.
Eight hopping rates are defined, consistent with the specifications of eqs. (36–37). So that the non-diagonal terms of $g^{ij}$ are properly reproduced, both nearest- and next-nearest-neighbor hops are required. The rate for each hopping event is

$$T_i(r \rightarrow r + \Delta r) = \frac{D_0}{\hbar^2} \left[ \frac{g(r + \Delta r)\hbar^2}{g(r)\hbar^2} \right]^{1/4} \times \frac{1}{2} [f(r) + f(r + \Delta r)] . \quad (38)$$

The function $f$ is given by

$$f = g^{11} - \epsilon, \text{ for } \Delta r = (\pm h, 0)$$
$$f = g^{22} - \epsilon, \text{ for } \Delta r = (0, \pm h)$$
$$f = (g^{12} + \epsilon)/2, \text{ for } \Delta r = (\pm h, \pm h)$$
$$f = (-g^{12} + \epsilon)/2, \text{ for } \Delta r = (\pm h, \mp h) , \quad (39)$$

with $\epsilon = |g^{12}|$. The transition rates in eq. (38) explicitly satisfy detailed balance for the equilibrium distribution limit $t \rightarrow \infty$ $P(r, t) = (\text{const}) \sqrt{g(r)}$. These rates give the correct average and mean-square displacements to $O(h)$, eqs. (36–37), when $\Delta t = 1/\sum T_i$. These results imply that the Monte Carlo procedure evaluates the differential eq. (3), and so eq. (141) can be used to calculate the mean-square-displacements. The procedure of ref. (18) is used to perform the simulation of this random process, where the particle is moved to one of the neighboring eight sites with probability $\Delta t T_i$, and time is incremented by $dt = -\Delta t \ln(x)$, where $x$ is a uniform random number, $0 < x \leq 1$.

The results of the numerical simulations are shown in Fig. 2. The calculations were performed for the case $\mu = \lambda$, $n = 2$, $h = 1$, and $\beta = 4$. The simulations were done on $4096 \times 4096$ lattices for a total of $500 000$ steps and averaged over $100$ samples. The strength of the disorder was varied between $0 < \gamma < 1.25$. For larger values of $\gamma$, the transition rates specified by eqs. (38) became negative at some of the lattice sites. Also shown is a fit to the functional form $\delta D/D_0 = 1 - ax$. The fit to the simulation data of $a = 0.01285 \pm 0.0051$ is in excellent agreement with the theoretical of result $a = 0.01326$ from eq. (45).

V. POSSIBLE ANOMALOUS DIFFUSION

The case $n = 0$ is interesting, as perturbation theory for the diffusion coefficient formally diverges. While this theory has the same upper critical dimension, $d_u = 2$, as the problem of diffusion of an ion in the electrostatic field of random, quenched charges $\tilde{\Pi}$, the interaction term, eq. (32), is quite different. In comparison to the analogous case for diffusion in the random potential (e.g. term $S_3$ of ref. (18) with $\tilde{\chi}_{\alpha\alpha}(k) = \tilde{\chi}(k)/k^2$), the term proportional to $\mu$ is new, as are the factors $-k_1^2 + 2|\mathbf{k}_1 k_2^2 - (\mathbf{k}_1 \cdot \mathbf{k}_2)|/|\mathbf{k}_1 + \mathbf{k}_2|^2$ in the term proportional to $\mu + \lambda$. Indeed, as we will see, the present interaction term is more difficult to analyze than is the analogous one from diffusion in a random potential. Formally, the case of $n \leq 0$ leads to large distortions of the lattice for arbitrarily small $\gamma$, which implies that the assumption of linear elasticity used to calculate the strain fields breaks down. We can, however, treat the dynamical behavior implied by eqs. (31) as an interesting mathematical question. A technical detail is that we supplement the correlation function eq. (29) with the condition $\tilde{\chi}(0) = 0$ so that the displacement fields of eq. (27) are well-defined for $k = 0$. This suppresses macroscopic size fluctuations of the sample.

Before applying renormalization group theory, the terms in the field theory must be known. The quartic interaction term, eq. (32), is known. The contribution to the propagator, eq. (33), while explicit, leads to a formal divergence of the short-time diffusion coefficient. Numerical simulations show that the local diffusivity tensor, $D_{00} g^{ij}$, can be large but is never vanishingly small. The locations of large local diffusivity, moreover, are isolated. The apparent divergence of $\delta D_{11}$ is, thus, simply the result of particles rapidly hopping away from a few isolated locations. These physical considerations suggest that the divergence of $\delta D_{11}$ is washed out by spatial averaging and is not important for the long-time dynamics. We can, therefore, assume a finite local diffusivity. Numerical simulations of the dynamics, to be described below, bear out this assumption of a finite short-time diffusivity. Indeed, a finite short-time diffusivity is assured for finite lattice sizes by the elimination of the $\tilde{\chi}(0)$ mode. The anomalous dynamics, then, is observed on finite lattices for time scales that are less than the characteristic time it takes to travel across the lattice.

We apply renormalization group theory to the action (31–32) to take into account the effects of nonzero $\gamma$. To one-loop order, self-energy and vertex diagrams are summarized in Figs. 5 and 6. The flow equations are inte-
FIG. 3: a) Diagram representing the propagator. The arrow points in the direction of increasing time, and double lines represent the bar fields. b) Disorder vertex $\gamma$.

grated to a time small enough so that perturbation theory applies. In this regime, matching theory is used to determine the constants of integration for the flow equations. Momenta in the range $\Lambda / b < k < \Lambda$ are integrated over, and the fields are rescaled by $\bar{a}(\bar{b}k, \bar{b}^{-1}t) = \bar{a}(k, t) / \bar{a}$ and $\bar{c}(\bar{b}k, \bar{b}^{-1}t) = \bar{c}(k, t) / \bar{a}$. The relations $\alpha = 1, \bar{a} = b^2$ are used to achieve a fixed point and to keep the time derivative in $S$ constant. The flow parameter is defined by $l = \ln b$. We determine the dynamical exponent, $z$, by requiring that the diffusion coefficient remain unchanged. Defining $\gamma_1^2 = \gamma \mu^2 / (2\mu + \lambda)^2$, $\gamma_3^2 = \gamma \mu (\mu + \lambda) / [2(2\mu + \lambda)^2]$, and $\gamma_3^2 \sim \gamma (\mu + \lambda)^2 / [4(2\mu + \lambda)^2]$, the contributions to the parameters from the one-loop diagrams of fig. 4 are

$$ \frac{d \ln D}{dl} = z - 2 - \frac{2}{\pi} (\gamma_1^2 + 2 \gamma_3^2) $$

$$ \frac{d \ln \gamma_1^2}{dl} = 2(z - 2) - \frac{4}{\pi} (\gamma_1^2 + 2 \gamma_3^2) $$

$$ \frac{d \ln \gamma_2^2}{dl} = 2(z - 2) - \frac{2}{\pi} (\gamma_1^2 + 3 \gamma_3^2 - 2 \gamma_1 \gamma_3) $$

$$ \frac{d \ln \gamma_3^2}{dl} = 2(z - 2) - \frac{4}{\pi} (\gamma_3^2 - 2 \gamma_1 \gamma_3) \cdot \quad (40) $$

From the requirement that the diffusion coefficient remain fixed, the dynamical exponent is

$$ z = 2 + \frac{2}{\pi} (\gamma_1^2 + 2 \gamma_3^2) \cdot \quad (41) $$

Using eq. (41) in eq. (40), the flow equations become

$$ \frac{d \ln \gamma_1^2}{dl} = 0 $$

$$ \frac{d \ln \gamma_2^2}{dl} = \frac{2}{\pi} (\gamma_1 + \gamma_3)^2 $$

$$ \frac{d \ln \gamma_3^2}{dl} = \frac{4}{\pi} (\gamma_1 + \gamma_3)^2 \cdot \quad (42) $$

As expected, the flow equations show that there are only two independent parameters, $\gamma_1$ and $\gamma_3$, resulting from renormalization of the two Lamé coefficients. In other words, the relation $\gamma_2^2(l) = \gamma_1(l) \gamma_3(l)$ is maintained under the renormalization.

Unexpectedly, however, the flow equations show that the $\gamma_2(l)$ and $\gamma_3(l)$ are growing. Indeed, these one-loop flow equations predict $\gamma_3(l)$ flows to infinity at a finite time corresponding to $l = [\pi / (2 \gamma_1^0 + 2 \gamma_3^0)] \ln [(\gamma_3^0 / \gamma_3^0) / (\gamma_0^0 / \gamma_0^0)]$. The divergence of this parameter implies that higher order terms must be kept in the flow equation to derive a controlled result. It may also be the case that terms higher order in $w^{\text{disloc}}$ must be kept in the expansion of the action (21).

If the renormalization of the parameters is assumed to be controlled by higher-loop corrections and small, the dynamical exponent can be used to determine the scaling exponent for the mean-square displacement at long times:

$$ \langle r^2(t) \rangle \sim \langle \text{const} \rangle t^{1-z} \cdot \quad (43) $$

The renormalized time flows as

$$ t(l^*) = t e^{-\int_0^{l^*} \langle z(l) dt \rangle} = t_0 \cdot \quad (44) $$

where the flow equations are stopped at $l^*$ so that $t_0 \approx b^2 / (4D_0)$. The renormalized mean-square displacement flows as

$$ \langle r^2(t) \rangle = e^{2t} \langle r^2[l(t), l] \rangle \cdot \quad (45) $$

Finally, at the matching

$$ \langle r^2[l(l^*), l^*] \rangle = 4Dt(l^*) \cdot \quad (46) $$

since the time is short enough so that the disorder does not significantly affect the motion of the particle. In
other words, it is assumed that at short times the diffusion coefficient remains finite, despite the formal appearance of \( \delta D_{ij} \) in eq. (33). Putting these matching results together with the dynamical exponent, the mean-square displacement is found to scale at long times as

\[
\langle r^2(t) \rangle \sim (\text{const})^{1/[2 + (\gamma^2 + 2 \beta^2)/2]}.
\]

(47)

To test whether anomalous scaling occurs in the full non-linear model, we perform numerical simulations. The transition rates from eqs. (38–39) cannot be used, as they are negative even for small values of \( \gamma \). We, therefore, develop a new strategy based upon the idea that diffusion locally follows a Gaussian probability distribution with mean and variance specified by eqs. (38) and the two eigenvalues of the matrix \( D_{ij}^g \). Defining the matrix \( w = (2D_0\Delta t g^{ij})^{1/2} \), the random displacements of the diffusing particle are given by the relations

\[
\begin{align*}
\Delta x &= \frac{D_0 \Delta t}{\sqrt{g}} \partial_j (\sqrt{g} g^{ij}) + w^{11} z_1 + w^{12} z_2 \\
\Delta y &= \frac{D_0 \Delta t}{\sqrt{g}} \partial_j (\sqrt{g} g^{ij}) + w^{21} z_1 + w^{22} z_2,
\end{align*}
\]

(48)

where \( z_1 \) and \( z_2 \) are independent, Gaussian random variables with zero mean and unit variance. This approach reproduces the Fokker-Planck equation (21) in the limit of a small lattice spacing and time increment. For a finite lattice spacing, the diffusion coefficient, and possibly the scaling exponent \( \delta \), contain discretization errors.

The results of numerical simulations with this scheme are shown in Fig. 5. The calculations were performed for the case \( \mu = \lambda, n = 0, h = 1, \) and \( \beta = 4 \). The simulations were done on \( 4096 \times 4096 \) lattices for a total of 1000000 steps and averaged over 100000 particles. Also shown is a fit to the functional form of eq. (21). The simulation results are approximately fit by \( (\gamma - 2)/\gamma = 1.02 \pm 0.28 \). If it is assumed that none of the parameters flow, the scaling exponent is given by \( (\gamma - 2)/\gamma = 2/(3\pi) \approx 0.2122 \). By comparison, the simulation results suggest that there is substantial positive renormalization of the parameters, as is suggested by eq. (22).

VI. DISCUSSION

A Fokker-Planck equation for diffusion on the surface of a crystal with topological defects, eq. (13), has been derived by two independent methods. As expected, the usual diffusion equation in curved space is derived. An additional assumption of \( \sqrt{g} = 1 \) of previous, approximate treatments \[4\] has also been removed in the present calculation through the use of the exact strain field eq. (28). The theory of random dislocations is shown to be equivalent to a theory of random disclinations, where a simple factor of \( k^2 \) relates the correlation functions of the two models of disorder, eqs. (28) and (30).

The field theory for disorder, eqs. (31–32), is explicitly shown to be distinct from that for diffusion of an ion in a random electrostatic potential field. One consequence of this difference is that the renormalization group flow equations are more involved to analyze, with one-loop results unable to render a controlled prediction.

Topological disorder slows down a diffusing particle, as shown by eq. (55). This reduced transport should be observable on the surfaces of crystals with quenched disclination or dislocation defects. While the effect is subtle, it would be an interesting one to observe experimentally. The present computer simulation results suggest such observations should be feasible.

For singular disorder, \( n \leq 0 \) in two dimensions, the model of topological disorder leads to subdiffusive motion of the particle. Of course, for such singular disorder, the assumption of linear elasticity breaks down. Moreover, the energy of a distribution of topological defects with net dipole moment becomes super-extensive due to large strain fields at the edges of the two-dimensional crystal \[10\]. Nonetheless, the suggestion that subdiffusion is the mathematical result of motion in the, possibly approximate, random displacement fields of linear elasticity theory is interesting. Renormalization group arguments are suggestive of such subdiffusion, although one-loop results are unable to capture the exponents quantitatively.

Numerical simulations accurate to all orders in the displacement fields suggest that the motion is, indeed, sub-diffusive. These numerical simulations suggest that there is significant renormalization of the disorder strength parameter, in contrast to the case of diffusion in random potential fields \[1\]. Interestingly, the renormalization of \( \gamma \) appears less significant for smaller values of \( \gamma \), although this may be because the crossover time for renormaliza-
tion is large for small $\gamma$ and longer than the observed simulation time. These simulations suggest a power law behavior of the mean square displacement, although localization at exceptionally long times cannot be ruled out, in principle.

VII. WHAT IF TORSION IS INCLUDED?

We here comment on the impact of the torsion term within the continuum theory of the diffusion equation. The torsion term is evaluated as

$$2T_{ik} = \left( \frac{\partial^2}{\partial r_k \partial r_i} \right) = -\epsilon_{ij} \frac{\partial^2}{\partial \sigma_\alpha} b_\alpha .$$

Expanding eq. (18) to linear order in $u$, we find that the interaction term, previously eq. (32), becomes

$$S_I = \frac{D^2}{2} \int dt_1 dt_2 \int_{k_1, k_2, k_3, k_4} \times (2\pi)^2 \delta(k_1 + k_2 + k_3 + k_4) \times \hat{a}(k_1, t_1) \hat{c}(k_2, t_1) \hat{a}(k_3, t_2) \hat{c}(k_4, t_2)$$

$$\times \left[ \left( 2\gamma_1 \frac{k^2_3}{|k_1 + k_2|^2} + \gamma_3 \frac{k_1 \cdot k_2 (k^2_3 + k^2_4) + 2k^2_3 k^2_4}{|k_1 + k_2|^4} \right) \times (k_1 + k_2) + \sqrt{n} \right]$$

$$(50)$$

Exactly the same theory is generated if the correlation function eq. (43) is used with the disclination displacements given by eq. (44). The inclusion of the torsion term has generated additional terms proportional to $\sqrt{k_2}$ and $\sqrt{k_4}$. Applying perturbation theory to $S_I$, we find that a mass term is generated, $\delta m = -2D_0 \gamma_1 \sqrt{\gamma}$. This term is exactly canceled by a mass term arising from the average of terms proportional to $(u_\text{disloc})^2$, which must be the case since the master equation (11) conserves probability. No contribution to the diffusivity is generated by the average of terms proportional to $(u_\text{disloc})^2$. From the average of $S_I$, we find an additional negative contribution to the diffusivity:

$$\delta D_{III} = -\frac{\gamma D_1 \Gamma(n/2)}{2\pi 2^{3n/2}} \left[ \frac{2(\mu + \lambda)}{(2\mu + \lambda)} \right] .$$

(51)

Within the approximation of the continuum diffusion equation, then, the torsion term generates an additional contribution to the effective diffusivity when $n > 0$. Note that this contribution is a result of correlated drift terms that exist solely within the cores of the defects. There is no reason to expect that this contribution is universal or even well-described by continuum theory.

For the mathematically interesting case of $n \leq 0$ we follow our previous numerical strategy. The random displacements of the diffusing particle are altered from eq. (18) to

$$\Delta x = \frac{D_0 \Delta t}{\sqrt{g}} \partial_j (\sqrt{g} g^{ij}) + D_0 \Delta t g^{j} T_j + w^1 z_j$$

$$\Delta y = \frac{D_0 \Delta t}{\sqrt{g}} \partial_j (\sqrt{g} g^{2j}) + D_0 \Delta t g^{2j} T_j + w^2 z_j .$$

(52)

To make use of this formula, we need an expression for $\partial r_i / \partial \sigma_\alpha$ that occurs in $T_j$. This is found as $\partial r_i / \partial \sigma_\alpha = A_{\alpha i}^{-1}$ where $A_{\alpha i} = \partial \sigma_\alpha / \partial r_i = \delta_{\alpha i} - \partial u_\alpha / \partial r_i$. In evaluating $T_j$, we use the first line of eq. (43). The results of numerical simulations with this scheme are shown in Fig. 5. The calculations were performed for the case $\mu = \lambda$, $n = 0$, $h = 1$, and $\beta = 4$. The simulations were done on 4096 x 4096 lattices for a total of 100000 steps and averaged over 100000 particles. Also shown is a fit to the functional form of eq. (18). The simulation results are approximately fit by $(z - 2)/\gamma = 0.49 \pm 0.04$.

There appears to be relatively little if any renormalization of $z$ away from the bare value. A power law behavior of the long-time mean square displacement in the presence of torsion is observed, although localization at exceptionally long times still cannot be ruled out.

It is clear that within the continuum assumption of the diffusion equation, the torsion term affects the dynamics. The contribution to the diffusion coefficient is explicit in eq. (51) for the case $n > 0$. For $n = 0$, the results shown in Fig. 5 differ from those without torsion in Fig. 3. Note that the results with torsion, as those without torsion, differ substantially from the approximate results.
of $\mathbb{R}$, noticeably through their dependence on the two Lamé coefficients.

VIII. CONCLUSION

We have given a treatment of the effect of topological disorder on transport properties. Within the lattice reconstruction predicted by linear elasticity theory, topological disorder is manifestly different from charged, potential-type disorder. The net effect of the defects, through local lattice expansion and contraction and global topological rearrangement of lattice connectivity, is an overall reduction of the transport. Interestingly, randomly placed dislocations, or randomly placed disclinations with no net disclinicity, lead to anomalous sub-diffusive behavior when the displacement fields of linear elasticity are used.
