**ABSTRACT**

Orthodontic retention is defined as maintaining teeth in optimal aesthetic and functional position after treatment. Despite the necessity of retention phase and the factors influencing the stability of the teeth after orthodontic treatment was discussed by the orthodontist for a long time, it is accepted that a retention phase is essential for stability of orthodontic treatment results nowadays. Therefore, the application of a suitable retention method is important both for prevention of relapse after orthodontic treatment and for increasing patient satisfaction. Removable appliances had been used for many years for retention purposes. Later, fixed retainers were introduced to prevent relapse as having a number of advantages, such as better aesthetics, no need for patient cooperation, effectiveness, and suitability for lifelong retention. However, their need for precise bonding technique, fragility, and tendency to cause periodontal problems by weakening oral hygiene are some of their disadvantages.

**Keywords:** Orthodontic retention, tooth stability, relapse, fixed retainer, lifelong retention

**INTRODUCTION**

Orthodontic retention is defined as maintaining teeth in optimal aesthetic and functional position after treatment (1). Retention is a treatment phase in which clinicians have not come to a consensus and rather shapes through years as the clinician gains experience (2). The necessity of retention phase has even been a debate among orthodontists for years (3). In the 19th century, the most important factor for stability of the teeth after orthodontic treatment was believed to be occlusion. Approaching the 20th century, Lundstrom (4) claimed that the most important factor for stability is apical base, whereas McCauley (5) emphasized the importance of canine and molar relationship. In 1944, Tweed (6) reported that incisor inclination plays a role, and that upright incisors help in maintaining better stability during retention. Nowadays, there is a strong acceptance that a retention phase is crucial for stability of treatment results. Furthermore, lifelong retention is advised in some cases (7).

Removable appliances have been used for many years for retention purposes. In the 1970s, fixed retainers were introduced to prevent relapse in the lower incisor area (8). These retainers that are bonded to the lingual faces of the teeth are increasingly preferred by orthodontists for being both aesthetic and easy to wear by patients for long-term use (9,10)146 boys. In a study published in 2002, it was reported that one-third of orthodontists preferred fixed lingual retainer in the mandible, whereas 5% preferred fixed retainers in the maxilla (11). In another study published in 2011, it was reported that fixed retainers are preferred by 42% of orthodontists in the mandible and 11% of orthodontists in the maxilla (12).
tal problems by weakening oral hygiene are some of their disadvantages.

In 1965, Newman (14) presented the direct bonding technique of orthodontic attachments. Later, in 1973, Kneirim (15) introduced the use of fixed retainers for orthodontic retention purposes for the first time. The wires that are used in the manufacturing of fixed retainers are categorized into generations since they have been introduced (16). These are the following:

- **1st generation**: These are 0.025–0.036 inch blue elgiloy or stainless steel round wires. These are bonded only to lingual surfaces of canines, and loops are bended at each end to increase retention.

- **2nd generation**: These are 0.032 inch triple-stranded wires and can be bonded to lingual surfaces of all anterior teeth. These multi-stranded wires substituted plain wires as they have higher elasticity that allows physiological movement of the teeth (17).

- **3rd generation**: These are 0.032 inch stainless steel or 0.030 inch gold-coated plain wires. Their ends are sandblasted with aluminum oxide to increase mechanic retention. They are bonded to canines only (18).

- **4th generation**: These are 0.0215 inch 5-stranded wires that can be bonded to all anterior teeth.

- **5th generation**: These are 0.032 inch, blue elgiloy plain wires that are sandblasted at the ends and bonded to canines only.

At the beginning, plain round or rectangular orthodontic wires were used as fixed retainers (1). In 1977, Zachrisson (19) presented the advantages of using multi-stranded wires as bonded retainers. Then, in 1982, Artun and Zachrisson (20) introduced the technique of bonding multi-stranded wires to canines only. Later, Zachrisson (21) applied triple-stranded wires to all anterior teeth in his studies. However, in his paper where he discussed his experience with fixed retainers for 20 years, he reported that 0.0215 inch 5-stranded wires serve better results based on failure rates observed in follow-up sessions (21) (Figure 1).

In the last 10 years, multi-stranded wires became more popular for bonded fixed retainers (1). Meanwhile, resin fiberglass bands were introduced as an alternative (22, 23). However, although they were more aesthetic and smaller in size, their higher long-term failure rates and inability to allow physiological tooth movements reduced their popularity as a choice for bonded fixed retainers (Figure 2).

In recent years, bonded retainers can be manufactured using CAD–CAM systems. The studies in this area are limited as this is a very new technology. The techniques and types of wires used for manufacturing bonded retainers using CAD–CAM technology vary for each firm. In one of the techniques used, the retainers are produced by bending of prefabricated wires by the handle of a machine. The SureSmile retainer (OraMetrix, Richardson, TX, USA) that is produced by this technique uses copper–nickel–titanium wires (24). Another technique is producing bond-
The indications for bonding fixed retainers to all teeth were defined by Zachrisson (28) as follows:

- cases in which median diastema is closed,
- cases with diastemas between the anterior teeth,
- adult patient with a potential for migration of the teeth after orthodontic treatment,
- cases with tooth loss or large diastemas in the maxilla before treatment,
- cases treated with mandibular incisor extraction,
- cases with severely rotated teeth before treatment,
- cases in which the position of a palatinally impacted canine is corrected.

The fixed retainers that are bonded to only canines are generally indicated when the anterior segment is moved toward the anteroposterior or lateral directions. If there is a risk of relapse for each tooth separately, then it will be wiser to bond the retainer to each tooth (1).

**Clinical Evaluation of Fixed Retainers**

Failure types, failure rates, and effects on periodontal health are the investigated issues in clinical studies related with bonded retainers.

**Failure Types of Fixed Retainers**

The reasons for failure of bonded fixed retainers include separation of tooth–adohesive interface, separation of wire–adohesive interface, breakage of retainer wire, and unwanted torque movements of the teeth caused by a retainer wire (29–33). It is reported that most of the failures are observed within the first 6 months of retainer use.

The most common failure type is separation of tooth–adohesive interface (29). The reported rate of this failure type in metal retainers is 3.5%–53%, whereas this rate changes from 11% to 51% in fiber retainers (30–33). The reason for separation of tooth–adohesive interface is almost always related with extreme biting forces caused by eating hard foods. Therefore, patients wearing fixed retainers should abstain from biting hard foods directly. On the other hand, breakage of retainer wire is usually related with metal fatigue that is observed in long-term retainer use.

It is mentioned that the reason for separation of retainer wires from adhesive materials may result from either inadequate use of adhesive materials during the bonding stage or loss of adhesive material from composite surface due to abrasion in long-term use. Larger amounts of adhesive usage is recommended to increase the resistance to abrasion (1).

The less common failure types are opening of spaces between the teeth and sometimes displacement of the teeth or occurrence of dehiscence due to unexpected torque movements although there is no separation of retainer from tooth surface (9,31,34–36). It is reported that passive adaptation of retainer wire to tooth surface, avoiding contamination of saliva during bonding, and abstaining from biting hard foods will increase the success rate of fixed retainers.

**Failure Rates of Fixed Retainers**

A number of studies investigating various types of retainer wires, adhesive materials, and bonding techniques used for fixed retainers can be found in the literature. There is a wide range for failure rates examined for each different type of fixed retainers. For stainless steel retainers, which are bonded to canines only, the failure rates are reported to be 13%–37.7% (27, 37–39). On the other hand, the failure rates are reported to be 9%–14% when they are bonded to six lower incisors (40, 41).

The failure rates for multi-stranded retainers that became popular in recent years for their advantages are reported to be 8.8%–46% (32, 33, 38, 42, 43). For resin fiberglass retainers, the failure rate was observed between 11% and 71%, and the risk of failure for maxilla was reported to be higher than that for mandible for all examined fixed retainer types (32, 33, 44).

**Effects of Fixed Retainers on Periodontal Health**

The biggest concern for bonded fixed retainers in long-term use is whether they make it more difficult to maintain oral hygiene and cause negative effects on periodontal health (8, 20, 37, 38, 45–48). However, no consensus is found about this subject when the literature is reviewed. There are studies that show that bonded fixed retainers cause increased plaque and calculus accumulation or gingival inflammation. There are also other studies that show no negative effect.

Artun (20) compared the effects of different types of fixed retainer wires on caries formation and periodontal health and reported that although fixed retainers cause more plaque accumulation, they do not cause caries. Levin et al. (45) showed that bonded fixed retainers cause increased plaque accumulation, gingival recession, and bleeding on probing. Pandis et al. (8) reported that as a result of long-term tissue irritation, bonded fixed retainers cause an increase in pocket depth, marginal gingival recession, and calculus accumulation. However, these results were related with long-term wearing of fixed retainers rather than the materials used (20). It was remarked that the proximal area beneath bonded fixed retainers was difficult to clean, thus more calculus was accumulated in this area (8, 46).

On the other hand, there are many studies that argue against these opinions. These studies revealed that even long-term wearing of fixed retainers caused no gingival tissue damage in most patients (37, 38, 47, 48).
Rody et al. (47) placed fixed retainers in the mandibular anterior teeth and reported that although there is an increase in plaque accumulation, periodontal health is not affected. Booth et al. (37) reported acceptable gingival values in the mandibular anterior teeth after long-term wear of fixed retainers. Another study reported a decrease in bone level and remarked that it was due to orthodontic treatment rather than type of retention protocol (49).

**CONCLUSION**

Even though there are controversial studies in the literature, it is evident that bonded fixed retainers complicate maintaining oral hygiene. In light of this information, it is crucial to inform patients about the importance of brushing and flossing in details. They should also avoid biting hard foods, be motivated to protect their dental health, and be encouraged not to miss their periodic check-ups during the retention phase of orthodontic treatment (50).
