The cross section of atomic electron Compton scattering $\gamma + e \rightarrow \gamma' + e'$ was measured in the 4.40–5.475 GeV photon beam energy region by the PrimEx collaboration at Jefferson Lab with an accuracy of 2% and less. The results are consistent with theoretical predictions that include next-to-leading order radiative corrections. The measurements provide the first high precision test of this elementary QED process at beam energies greater than 0.1 GeV.

I. INTRODUCTION

Quantum electrodynamics (QED) is one of the most successful theories in modern physics; and the Compton scattering of photons by free electrons $\gamma + e \rightarrow \gamma' + e'$ is the simplest and the most elementary pure QED process. The lowest-order Compton scattering diagrams (see Fig. 1) were first calculated by Klein and Nishina in 1929 \[1\] and by Tamm in 1930 \[2\]. Higher-order contributions arising from the interference between the leading order single Compton scattering amplitude and the radiative and double Compton scattering amplitudes were calculated in the 1950s \[3\],\[4\]. Figure 1 shows the Feynman diagrams illustrating these two processes. They were subsequently re-evaluated in the 60s and early 70s to make them amenable for calculation using modern computational techniques \[5\]-\[7\]. Corrections to the leading order Compton total cross section at the level of a few percent are predicted for beam energies above 0.1 GeV \[6\], hence the next-to-leading order (NLO) corrections are important when studying Compton scattering at these energies.

Experiments performed so far were mostly in the energy region below 0.1 GeV; a few experiments probed the 0.1-1.0 GeV energy range with a precision of 10–15\% \[17\]-\[20\]. Only one experiment \[21\] measured the Compton scattering total cross section up to 5.0 GeV using a bubble-chamber detection technique. The experimental uncertainties for energies above 1 GeV were at the level of 20–70\%. Due to the lack of precise data, higher order corrections to the Klein-Nishina formula have never been tested experimentally. This paper reports on new measurements of the Compton scattering cross section with a precision of 1.7\% performed by the PrimEx collaboration at Jefferson Lab (JLab) for two separate running periods. The total cross sections in a forward direction on $^{12}$C and $^{28}$Si targets were measured in the 4.400–5.475 GeV-energy region. The precision achieved by this experiment provides, for the first time, an important test of the QED prediction for the Compton scattering process with corrections to the order of $O(\alpha)$, where $\alpha$ is the fine structure constant. In this article, we will summarize the theoretical calculations (Sec. II), describe our experimental procedure (Sec. III), and present the results of the comparison between the data and the theoretical predictions (Sec. IV).

II. A SUMMARY OF THEORETICAL CALCULATIONS

The leading order Compton scattering cross section (see Fig. 1, top) was first calculated by Klein and Nishina \[1\] and the result is known as the Klein-Nishina formula \[22\]:

$$
\frac{d\sigma}{d\Omega} = \frac{r_e^2}{2} \left[ 1 + \frac{1}{1 + \gamma(1 - \cos \theta)} \right] \left[ 1 + \cos^2 \theta + \frac{\gamma^2(1 - \cos \theta)^2}{1 + \gamma(1 - \cos \theta)} \right]
$$

where $r_e$ is the classical electron radius, $\gamma$ is the ratio of the photon beam energy to the mass of electron, and $\theta$ is the photon scattering angle. This formula predicts that the Compton scattering at high energies has two basic features: (i) the total cross section decreases with increasing beam energy, $E$, as approximately $1/E$, and (ii) the differential cross section is sharply peaked at small angles relative to the incident photons.

![Fig. 1: (Top) The lowest-order Feynman diagrams for single Compton scattering. (Bottom) Typical radiative correction (Left), and double Compton scattering contributions (Right) to single Compton scattering.](image1)

The theoretical foundation for the next-to-leading order radiative corrections to the Klein-Nishina formula had been well established by early 70s. The radiative corrections to $O(\alpha)$ were initially evaluated by Brown and Feynman \[3\] in 1952. This correction is caused by two types of processes. The first type, a virtual-photon correction, arises from the possibility that the electron may emit and reabsorb a virtual photon in the scattering process (see bottom left panel of Fig. 1). The second type is a soft-photon double Compton effect, in which the energy of one of the emitted photons is much smaller than the electron mass ($\omega_2 < \omega_{2\text{max}} \ll m_e$, where $\omega_2$ is the energy of the additional photon, $\omega_{2\text{max}}$ is a cut-off energy, and $m_e$ is the electron mass), as shown in the bottom right panel of Fig. 1. These two contributions...
must be taken into account together since it is impossible to separate them experimentally. Moreover, the infrared divergence term from the virtual-photon process is canceled by the infrared divergence term in the soft-photon double Compton process, resulting in a finite physically meaningful correction \(\delta^{SV}\). The value of \(\delta^{SV}\), where \(SV\) stands for \(S(\text{oft})\) and \(V(\text{virtual})\), is predicted to be negative as described by Eq. (2.6) and Eq. (2.15) in [6].

On the other hand, a hard-photon double Compton effect occurs when both emitted photons in the double Compton process have energies larger than the cut-off energy, \(\omega_{2\text{max}}\). When comparing the experimental result with the theoretical calculation, one must also take into account the contributions from the hard-photon double Compton effect since the experimental apparatus has finite resolutions leading to limitations on the measurements of both energies and angles [6]. The differential cross section of the double Compton effect was initially calculated by Mandl and Skyrme [4], and the total cross section of the Hard-photon Double Compton process \(\delta^{HD}\) is described by Eq. (6.6) in reference [6]. \(^1\) and its value is predicted to be positive. Summing up \(\delta^{SV}\) and \(\delta^{HD}\), the total NLO correction to the total cross section is predicted to be a few percent for photon beam energies up to 10 GeV.

In order to interpret the experimental results and compare with the theoretical predictions, one needs to develop a reliable numerical method to integrate the cross section and calculate the radiative corrections incorporating the experimental resolutions. The latter is critical in calculating the contribution from the hard photon double Compton effect correctly. As discussed above, the corrections are divided into two types \(\delta^{SV}\) and \(\delta^{HD}\) depending on whether the energy of the secondary emitted photon is less or greater than an arbitrary energy scale, denoted by \(\omega_{2\text{max}}\), which should be much smaller than the electron mass [6]. Since the physically measurable cross section contains the corrections from both types, the final integrated total cross section must be independent of the values of \(\omega_{2\text{max}}\). Two different methods had been developed to prove this independence.

The first method [8] is based on the BASES/SPRING Monte Carlo simulation package [2]. BASES uses the stratified sampling method to integrate the differential cross section, and SPRING uses the probability information obtained during the BASES integration to generate Compton events. The parameter \(\omega_{2\text{max}}\) does not enter the differential cross section explicitly but is contained in the limits of integration over the energy. For a consistency check, the total cross section was calculated with several values of \(\omega_{2\text{max}}\). While the calculated total Klein-Nishina cross section corrected with the virtual and soft photon processes \(\sigma_{SV}\) as well as the total hard photon double Compton cross section \(\sigma_{HD}\), both, depend on the \(\omega_{2\text{max}}\) parameter, the sum of the two corrections \(\sigma_{SV} + \sigma_{HD}\) is independent, within 0.1%, of the choice of \(\omega_{2\text{max}}\), as expected.

The second numerical method was developed by M. Konchatnyi [10], where the parameter \(\omega_{2\text{max}}\) is analytically removed from the integration. The total Compton cross section on \(^{12}\text{C}\) with radiative corrections calculated using both numerical methods [8] [10] were compared with each other were also compared to the values obtained from and also to the XCOM [11] database of the National Institute of Standards and Technology (NIST). They are in good agreement to within 0.5%, with the higher order corrections to the leading-order Klein-Nishina formula are about 4% for the beam energy in the 5 GeV region. In the data analysis described below, the BASES/SPRING method is used to calculate the radiatively corrected cross section and to generate events for the experimental acceptance study.

### III. EXPERIMENTAL PROCEDURE

![FIG. 2: Diagram, not to scale, of the experimental setup.](image)

The pair spectrometer placed between the target and the helium bag, had the magnet turned off during the Compton experiment.

The atomic electron Compton scattering process \(\gamma + e \rightarrow \gamma' + e'\) was measured using the apparatus built for the PrimEx experiment [12], which aimed to measure the \(\pi^0\) lifetime and was performed over two run periods in 2004 and 2010, in Hall B at JLab. The Compton scattering data were collected periodically, once per week during both running periods. The primary experimental equipment included (see Fig. 2): (i) the existing Hall B high intensity and high resolution photon tagger [13], which provides the timing and energy information of incident photons up to 6 GeV; (ii) solid production targets [14]: \(^{12}\text{C}\) (5% radiation length), used during the first running period, and \(^{12}\text{C}\) (8% radiation length) and \(^{28}\text{Si}\) (10% radiation length) added in the second running period; (iii) a pair spectrometer (PS), located downstream of the production target, to continuously

---

\(^1\) We note that a factor of 1/4 is missing in this equation.
measure the relative photon tagging ratio \( \text{15} \), and consequently the absolute photon flux, which was obtained by normalizing to the absolute photon tagging efficiency measured periodically with a total absorption counter (TAC) at low beam intensities (not shown in Fig. 2); (iv) a 118 \( \times \) 118 cm\(^2\) high resolution hybrid calorimeter (HyCal \( \text{16} \)) with 12 scintillator charge particle veto counters, which were located \( \sim 7 \) in downstream of the target, to detect forward scattered electromagnetic particles; and (v) a scintillator fiber based photon beam profile and position detector located behind HyCal for online beam position monitoring (not shown in Fig. 2).

To minimize the photon conversion and electron multiple scattering, the gap between the PS magnet and the HyCal was occupied by a plastic foil container filled with helium at atmospheric pressure. The energies and positions of the scattered photon and electron were measured by the HyCal calorimeter. In conjunction with the beam energy (4.9-5.5 GeV during the first experiment and 4.4-5.3 GeV during the second one), which was measured by the photon tagger, the complete kinematics of the Compton events was determined. During the Compton runs the experimental setup was identical to the one used for the \( \pi^0 \) production runs, except for the pair spectrometer magnet being turned off to allow detection of both scattered photons and recoiled electrons in the calorimeter. The use of the same experimental apparatus, as well as the similar kinematics allowed the measurement of the Compton cross section to be employed as a tool to verify the systematic uncertainty of the \( \pi^0 \) experiments.

A coincidence between the photon tagger in the energy interval of 4.4–5.5 GeV and the HyCal calorimeter with a total energy deposition greater than 2.5 GeV formed an event trigger. Only the experimental result from the higher beam energy (4.4–5.49 GeV) is presented in this report. The event selection criteria were: (i) the time difference between the incident photon, \( t_{\text{Tag}} \) and the scattered particles detected by the HyCal calorimeter, \( t_{\text{HyCal}} \) had to be \( |t_{\text{Tag}} - t_{\text{HyCal}}| < 5 \sigma_t \), where \( \sigma_t =1.03 \text{ ns} \) is the timing resolution of the detector system. (ii) the difference in the azimuthal angle between the scattered photon and electron had to be \( |\Delta \phi| < 5 \sigma_\phi \), where \( \sigma_\phi =7^\circ \) is the azimuthal angular resolution for the first running period, (for the second running period a target dependent resolution of \( \sigma_\phi =4 - 4.7^\circ \) was used); (iii) the reconstructed reaction vertex position was required to be consistent with the target thickness and position; (iv) the spatial distance between the scattered photon and electron as detected by the HyCal calorimeter had to be larger than a photon energy dependent minimum separation resulting from the reaction being elastic; the minimum separation of 16 cm for the first running period and \( R_{min}(E) =19.0 - 1.95 \times (4.85-E) \) for the second running period; and (v) the difference between the incident photon energy as measured by the tagger, \( E_{\text{Tag}} \) and the reconstructed incident photon energy, \( E_{\text{HyCal}} \), had to be \( |E_{\text{Tag}} - E_{\text{HyCal}}| < 1 \) (0.4) GeV for the first (second) running period. In the event reconstruction, the measured energy of the more energetic scattered particles (photon or electron) and the coordinate information of both scattered particles detected by the calorimeter were used. The offline energy detection threshold per particle in the HyCal calorimeter was 0.5 GeV.

![FIG. 3: An example of the yield fit, with background shown in red, for the highest energy bin.](image)

To extract the Compton yields, the signal and background events (at a level of several percent of the yield) were separated for every incident photon energy bin (with a width of \( \sim 1\% \) of the nominal beam energy). The background originating from the target ladder and housing was determined using data from dedicated empty target runs, and the yield from these runs were normalized to the beam current and subtracted away. The remaining events that passed all of the five selection criteria described above were used to form an elasticity distribution, \( \Delta E = E_0 - (E_\gamma + E_e) \), where \( E_\gamma \) and \( E_e \) are the scattered photon and electron energies, which were either measured (the first experiment) or calculated, using the Compton scattering kinematics, (the second experiment), and \( E_0 \) is the measured energy of the incident photon. The elasticity distribution was then fit to the simulated signal and background distributions, using a maximum likelihood method \( \text{23} \). Their overall amplitudes were parameters in the fit, as shown in Fig. 3.

The signal was generated by a Monte Carlo simulation employing the BASES/SPRING package as described in Sec. II \( \text{8, 9} \), which included the radiative processes and the double Compton contribution. The simulated signal events were propagated through a GEANT-based simulation of the experimental apparatus and then processed using the same event reconstruction software that was used to extract the experimental yield. The shape of the background was modeled by the accidental events alone for the first running period, while the pair production channel was also included for the second running period. The accidental background was selected from the data using the events that were outside the coincidence time.
window, from $|t_{\text{Tag}} - t_{\text{HyCal}}| > 5\sigma_t$, but satisfied the remaining four criteria described above. The pair production contribution was generated using the GEANT simulation toolkit with its results handled in the same manner as the experimental yield. The amplitude from the maximum likelihood fit was then used to subtract the background from the experimental yield for each incident photon energy bin, giving the Compton yield.

V. RESULTS

![Graph showing Compton cross sections for $^{12}$C and $^{28}$Si targets.]

**FIG. 4:** The Compton cross sections measured on atomic electrons of $^{12}$C and $^{28}$Si targets. The dashed curve corresponds to the Klein-Nishina calculation. The solid curve is the result of next-to-leading order calculation. Bold gray error bars are systematic uncertainties and thin black error bars are statistical uncertainties.

The Compton scattering total cross sections (TABLE [I]) were obtained by combining the extracted Compton yields with the luminosity and detector acceptance. Figure 4 shows the total Compton scattering cross sections from the first and the second running period, respectively. The extracted cross sections are compared to a next-to-leading order calculation for both running periods. All the results agree with the theoretical calculations within the experimental uncertainties.

The average total systematic uncertainty for each data point is 1.5% for the first running period and is 1.22 - 1.79% for the second running period depending on the target (lowest for the 5% $^{12}$C target and highest for the 10% $^{28}$Si target). The breakdown of the uncertainties is summarized in Table [I]. The uncertainty in the photon flux is the largest source of uncertainty. It was determined from the long term overall stability of the beam, data acquisition live time, and tagger false count rate. The uncertainty due to background subtraction was estimated from the variation in the fitting uncertainty with changes to the shape of the background distributions. The geometrical acceptance uncertainty was estimated from the variation in the simulated yields with small changes to the experimental geometry. The target thickness uncertainty was 0.05% for the 5% radiation length $^{12}$C target. The uncertainty was higher for the thicker targets used during the second running period: 0.11% for the 8% radiation length $^{12}$C target and 0.35% for the 10% radiation length $^{28}$Si target.

![Table showing estimated systematic uncertainties.]

**TABLE I:** Estimated systematic uncertainties, in percent, for each target over the entire energy range.

| Source Of Uncertainty           | $^{12}$C | $^{12}$C(5%) | $^{12}$C(8%) | $^{28}$Si |
|--------------------------------|---------|-------------|-------------|---------|
| photon flux                    | 1.0     | 0.82        | 0.82        | 0.82    |
| target composition, thickness  | 0.05    | 0.05        | 0.11        | 0.35    |
| coincidence timing             | 0.05    | 0.49        | 0.68        | 0.60    |
| coplanarity                    | 0.08    | 0.51        | 0.66        | 0.71    |
| geometrical acceptance        | 0.00    | 0.29        | 0.91        | 0.02    |
| background subtraction         | 0.72    | 1.07        | 1.32        | 1.31    |
| HyCal energy response          | 0.5     | 0.5         | 0.5         | 0.5     |
| total                          | 1.5     | 1.6         | 1.9         | 2.0     |

VI. CONCLUSION

In conclusion, the total cross section for Compton scattering on $^{12}$C and $^{28}$Si, in the 4.400 - 5.475 GeV-energy range was measured with the PrimEx experimental apparatus. The results are in excellent agreement with theoretical prediction with NLO radiative corrections. Averaged over all data points per target, the total uncertainties were 1.7% for the first running period, and 1.3%, 1.5%, and 2.5% for the second running period (for 5% and 8% $^{12}$C, and $^{28}$Si targets, respectively - see Table [I]). This measurement provides an important verification of the magnitude and the sign of the radiative effects in the Compton scattering, which determined and separated from the leading order process for the first time. We conclude that this measurement constitutes the first confirmation that the QED next-to-leading order prediction correctly describes this fundamental process up to a photon energy, $E_\gamma$, of 5.5 GeV within our experimental precision.
