Abstract

We address in this paper the problem of constructing embeddings of planar graphs satisfying declarative, user-defined topological constraints. The constraints consist each of a cycle of the given graph and a set of its edges to be embedded inside this cycle and a set of its edges to be embedded outside this cycle. Their practical importance in graph visualization applications is due to the capability of supporting the semantics of graphs. Additionally, embedding algorithms for planar graphs with topological constraints can be combined with planar graph drawing algorithms that transform a given embedding into a topology preserving drawing according to particular drawing conventions and aesthetic criteria.

We obtain the following main results on the planarity problem with topological constraints. Since it turns out to be NP-complete, we develop a polynomial time algorithm for reducing the problem for arbitrary planar graphs to a planarity problem with constraints for biconnected graphs. This allows focusing on biconnected graphs when searching for heuristics or polynomial time subproblems. We then define a particular subproblem by restricting the maximum number of vertices that any two distinct cycles involved in the constraints can have in common. Whereas the problem remains NP-complete if this number exceeds 1, it can otherwise be solved in polynomial time. The embedding algorithm we develop for this purpose is based on the reduction method.

1 Introduction

Most research in the graph drawing field has focused so far on developing algorithms that produce drawings of graphs according to particular drawing conventions and aesthetic criteria (see [5], [6], [11] and [23]). Common drawing conventions require, for instance, the vertices to have integer coordinates, the edges to be polylines or straight lines or to be composed of straight line segments parallel to one of the coordinate axes. Aesthetic criteria are in general optimization goals such as minimizing the number of edge crossings, maximizing the minimum distance between vertices or, in case of polyline drawings, minimizing the number of bends. Both drawing conventions and aesthetic criteria are intended to ensure readability of the drawings. They can be seen as geometric constraints implicit to the drawing algorithms.

Many applications, however, need a visualization of graphs satisfying user-defined constraints to emphasize certain semantical aspects. Visual languages [27], for instance, may require some subgraphs to be drawn with a predefined shape to support their semantics. And in VLSI design [14] it is often necessary to have a graph layout where certain vertices are arranged in a group or cluster [21]. Although “the study of constraints is a strategic research direction for the graph drawing field” [22], there are only few graph drawing approaches allowing the user to define constraints. A survey of these approaches and those drawing algorithms that can be modified to support some sort of constraints is given in [22]. Again, the resulting constraints are primarily geometric and most of them are covered by the approach of [15] which supports the specification of arithmetic linear equality and inequality constraints on the coordinates of the vertices.

These approaches to constrained graph drawing have often the disadvantage of not drawing a planar graph without crossings, i.e. as a planar embedding. For graph planarity without constraints there are many testing and embedding algorithms developed so far: from conceptually simple procedures such as [4] (also briefly described in [1]) to more involved linear time procedures such as the path addition embedding algorithm presented by Mehlhorn and Mutzel [18] based on the planarity testing procedure of Hopcroft and Tarjan [16] or the vertex addition embedding algorithm presented by Chiba et al. [3] based on the planarity testing procedure of Booth and Lueker [2]. However, the problem of constructing a planar embedding according to explicit constraints has obtained only little attention so far, despite its impact to planar graph theory and practice. An interesting approach to constrained graph embedding presented in [19] is the problem of finding a planar embedding such that the user’s preferences for facial cycles are satisfied. The preferences, or constraints, are specified by a cost function on the cycles of the graph. In an embedding that satisfies these constraints the overall costs of its facial cycles are minimized. Another approach is the construction of planar embeddings for clustered graphs [12]. A clustered graph is a graph with a user-defined hierarchical structure over the vertices such that each level decomposes the graph into disjoint clusters. In a planar drawing of a clustered graph a cluster is represented by a simple region.
containing exactly the vertices that belong to this cluster. Additionally, edges are allowed to intersect the boundaries of the regions only once; in particular, edges connecting vertices of the same cluster must be inside the corresponding region. The embedding algorithm developed in [12] requires the vertices of each cluster to induce a connected graph. As shown in [9] and [10], these embeddings can be further transformed into drawings according to specific drawing conventions while preserving their cluster structure. Since many drawing procedures for planar graphs need a particular embedding (more precisely, a combinatorial representation of an embedding) as input and produce drawings of the same topology, the construction of embeddings satisfying given constraints can be used as a preprocessing step for a wide range of planar graph drawing algorithms.

This paper is devoted to planar graph embedding with topological constraints; it considerably extends the previous work in [8]. We define a topological constraint for a graph to consist of some of its cycle and a set of its edges to be embedded inside this cycle and a set of its edges to be embedded outside this cycle. These constraints are clearly topological since topological transformations of the plane preserve their validity. Note that we build constraints by sets of edges instead of sets of vertices. If some vertex is to be embedded inside or outside a given cycle, the corresponding topological constraint can be defined by using an edge incident to this vertex (if the vertex is isolated, it must be replaced by some new edge for the time of the embedding process). To see that in some situations vertex sets would be insufficient, think of, e.g., Hamilton cycles: the diagonals of a Hamilton cycle can be embedded inside or outside, but there is no vertex left to constitute a topological constraint.

The topological constraints are useful in graph embedding whenever the inner and outer regions of cycles have an intrinsic or user-defined semantics. Graphs whose vertices and edges represent spatial entities such as road maps or subway maps often induce some natural meaning to the faces and regions of their embeddings as well. In this case, topological constraints can be defined to ensure that the embedded graph preserves some important topological relationships. Generally, these constraints can be used to impose some structure on the embedding to be constructed. Consider in Fig. 1 the transition diagram of a finite automaton accepting the language \((a(cde)^*bz+f(hij))^*gz)^*\). The main components of this expression are \(a(cde)^*bz\) and \(f(hij))^*gz\), each representing a cyclic walk starting and ending in \(q_0\). Moreover, each component contains a subcomponent \((cde)^*\) and \((hij)^*\) representing cyclic walks starting and ending in \(q_1\) and \(q_6\), respectively. To reflect this structure in the diagram, it makes sense to draw the cycles \(q_0, q_1, q_7\) and \(q_0, q_6, q_7\) representing the main components into disjoint regions, but to draw the cycles \(q_1, q_3, q_2\) and \(q_6, q_5, q_4\) representing the corresponding subcomponents inside \(q_0, q_1, q_7\) and \(q_0, q_6, q_7\), respectively. These requirements can be expressed exactly by topological constraints. Last but not least, a topological constraint allows one to specify a cycle to be an inner or outer facial cycle just by postulating the former or latter set, respectively, to consist of all edges not belonging to that cycle.

The outline of the paper is as follows. Recalling in Sect. 2 the required defi-

nitions and results of planar graph theory, we show in Sect. 3 NP-completeness
of the problem of deciding whether a graph has an embedding satisfying a given
set of topological constraints. In contrast, we present a linear time embedding
algorithm for triconnected graphs. Section 4 is concerned with developing a
polynomial time procedure for reducing the embedding problem with topologi-
cal constraints to biconnected graphs. This can be particularly useful in search-
ing for tractable subproblems. We introduce in Sect. 5 a particular subproblem
defined by the maximum number of vertices two distinct cycles involved in the
constraints have in common. Whereas this problem remains NP-complete if
this number exceeds 1, we develop a polynomial time algorithm for generating
a required embedding if this number is 0 or 1. Finally, we conclude with Sect. 6.

2 Preliminaries

Assuming familiarity with basic graph terminology (see [1] and [7]), we recall
in this section the required fundamentals on planar graphs. For a thorough
presentation of planar graph theory we refer the reader to [24], [7] and [20].

Unless otherwise stated, all graphs are finite, simple and undirected. The
set of vertices and edges of a graph \(G\) are denoted \(V(G)\) and \(E(G)\), respectively.
Paths and cycles in a graph are always simple, i.e. their inner vertices are pair-
wise distinct. A cycle \(C\) in \(G\) is induced if any edge of \(G\) joining two vertices
of \(C\) is already an edge in \(C\). Moreover, \(C\) is non-separating if the number of
components of \(G\) does not increase when deleting \(C\) from \(G\). A block means a
maximal connected subgraph without a cutvertex, i.e. a maximal 2-connected
subgraph or a bridge or an isolated vertex. If \(A\) denotes the set of cutvertices
of \(G\) and \(B\) denotes the set of its blocks, then the block graph of \(G\) is defined on
\(A \cup B\) by the edges \(aB\) with \(a \in B\) for \(a \in A\) and \(B \in B\). Note that the block
graph of a connected graph is always a tree.

A plane graph \((V, E)\) consists of a finite set \(V \subseteq \mathbb{R}^2\) and a finite set \(E\) of
Jordan curves connecting two points of \(V\) such that any two points are connected
by at most one curve and the interior of a curve contains no point of \( V \) and no point of any other curve. These points and curves are again called vertices and edges, respectively, since all graph notions can also be applied to plane graphs. If there is an isomorphism between an abstract graph \( G \) and a plane graph \( \tilde{G} \), we call \( \tilde{G} \) an embedding of \( G \) in the plane. A graph is planar if it has an embedding in the plane. In the sequel, \( \tilde{G} \) always denotes an embedding of the graph \( G \) and for subgraphs \( H \subseteq G \) we often denote the restriction of \( G \) to \( H \) simply by \( \tilde{H} \).

Every plane graph \( G \) divides \( \mathbb{R}^2 \setminus G \) into disjoint open arcwise connected regions called faces of \( G \); the unbounded one is the outer face and the bounded ones are the inner faces. If a cycle \( C \) of \( G \) is the boundary of some face, we call \( C \) a facial cycle; depending on whether \( C \) is the boundary of an inner or outer face, we call \( C \) an inner or outer facial cycle, respectively. Any cycle \( C \) divides \( \mathbb{R}^2 \setminus C \) into two open arcwise connected regions; the bounded one is the interior of \( C \), denoted by \( \text{int} C \), and the unbounded one is the exterior of \( C \), denoted by \( \text{ext} C \). The closure of \( \text{int} C \) and \( \text{ext} C \) is denoted by \( \text{Int} C \) and \( \text{Ext} C \), respectively.

Given a graph \( G = (V, E) \) the edge space \( E(G) \) of \( G \) is the vector space over the 2-element field \( \mathbb{F}_2 = \{0, 1\} \) formed by the set of all subsets of \( E \) and the sum \( A \oplus B = (A \setminus B) \cup (B \setminus A) \) for \( A, B \subseteq E \). The cycle space \( C(G) \) is the subspace of \( E(G) \) generated by the cycles of \( G \) — more precisely, by their edge sets. The elements of \( C(G) \) are unions of edge-disjoint cycles of \( G \). Suppose \( \tilde{G} \) is an embedding of a 2-connected planar graph \( G \) and \( F' \) is the set of all facial cycles of \( G \). Then, as follows from MacLane’s planarity criterion [17], \( F = F' \setminus \{F\} \) forms a basis of \( C(G) \) for any \( F \in F' \) and \( F \) is the sum of all cycles in \( F \). There is always an embedding of \( G \) where \( F \) is the set of inner facial cycles and \( F \) the outer facial cycle. We often make use of the fact that the edges of \( G \) contained in \( \text{Int} C \) for some cycle \( C \subseteq G \) are exactly the edges of those inner facial cycles of \( G \) whose sum is \( C \). Moreover, any two embeddings of \( G \) are topologically equivalent if they coincide in their outer facial cycle and their set of inner facial cycles (see [7]). We can thus represent a particular 2-connected embedding up to topological equivalence just by its outer facial cycle and the set of its inner facial cycles. If in addition \( G \) is 3-connected, the facial cycles of \( G \) can be identified combinatorially as the induced non-separating cycles in \( G \), as proved by Tutte [26]. This allows representing any embedding of \( G \) just by its outer facial cycle because all these embeddings have the same facial cycles.

Finally, we introduce a notion that plays a fundamental role in graph embedding algorithms following the principle of path addition. Suppose \( H \) is a subgraph of \( G \). Then an \( H \)-component of \( G \) is either an edge (together with its ends) in \( E(G) \setminus E(H) \) joining two vertices of \( H \) or it is a connected component of \( G \setminus H \) together with all edges (and their ends) of \( G \) joining this component to \( H \).\(^1\) The vertices of an \( H \)-component in \( H \) are its vertices of attachment. Suppose \( C \) is a cycle in \( G \). Vertices of attachment of a \( C \)-component, provided that there are at least two, divide \( C \) into edge-disjoint paths, called segments. We say

\(^1\)This definition follows [24]. One can find elsewhere in the literature various notions for \( H \)-components, e.g. bridges in [1].
that two \( C \)-components avoid each other if either one of them has fewer than two vertices of attachment or all vertices of attachment of one \( C \)-component lie in a single segment of the other \( C \)-component; otherwise they overlap. The overlap graph \( G_C \) of \( C \) in \( G \) is defined as the graph whose vertices are the \( C \)-components of \( G \) such that two vertices are adjacent iff the corresponding \( C \)-components overlap. Overlap graphs can be used even for characterizing planar graphs: by Tutte’s theorem [25] a graph is planar iff the overlap graph of each of its cycle is bipartite.

3 Topological Constraints

In this section we introduce topological constraints and present a criterion for graphs having an embedding that satisfies such constraints. We also show some basic properties of the computational problem of finding these embeddings: whereas this problem is in general NP-complete, it can be solved in linear time for 3-connected graphs.

**Definition 1** Let \( G \) be a graph and \( T \) be a set of triples \( T_i = \langle C_i, \text{In}_i, \text{Out}_i \rangle \) such that \( C_i \) is a cycle in \( G \), \( \text{In}_i, \text{Out}_i \subset E(G) \setminus E(C_i) \), \( \text{In}_i \cup \text{Out}_i \neq \emptyset \) and \( \text{In}_i \cap \text{Out}_i = \emptyset \). These triples are called topological constraints for \( G \).

An embedding \( \tilde{G} \) of \( G \) satisfies \( T \) if for each constraint \( T_i \in T \) all edges of \( \text{In}_i \) are contained in \( \text{int} \tilde{C}_i \) and all edges of \( \text{Out}_i \) are contained in \( \text{ext} \tilde{C}_i \); such an embedding is called a \( T \)-embedding. Moreover, \( G \) is \( T \)-planar if \( G \) has a \( T \)-embedding.

Obviously, \( T \)-planar graphs are necessarily planar; thus we only consider planar graphs. Given a planar graph \( G \) and a set \( T \) of topological constraints for \( G \), \( n \) always denotes the number of vertices of \( G \), \( m \) denotes the number of edges where \( m \leq 3n - 6 \) and \( t \) denotes the number of constraints in \( T \). Note that \( t \) can be exponential in \( n \). The relevant parameters of the problem of finding a \( T \)-embedding of \( G \) are therefore \( n \) and \( t \). Since each constraint \( T_i \) consists of at most \( m \) edges, the input length of any instance can be assumed to be \( O(nt) \). For convenience, if \( C \) is a cycle \( C_i \) occurring in some constraint, we often write \( \text{In}_C \) and \( \text{Out}_C \) instead of \( \text{In}_i \) and \( \text{Out}_i \), respectively.

Due to the additional requirements on embeddings, one cannot hope for a simple Kuratowski-like criterion for \( T \)-planarity. In contrast to classical planarity, \( T \)-planarity of a graph cannot be simply reduced to its components or blocks either; even the required topological relationships between its components can get complex as we will see in the next section. To characterize \( T \)-planarity in Theorem 1, we make use of some properties of 3-connected planar graphs given in Sect. 2. This theorem is illustrated in Fig. 2.

**Theorem 1** Let \( G \) be a graph and \( T \) be a set of topological constraints. Then, \( G \) is \( T \)-planar iff there is a 3-connected planar graph \( G' \) with \( G \subseteq G' \) and \( V(G) = V(G') \) and a basis \( F \) of \( \mathcal{C}(G') \) consisting of induced non-separating cycles of \( G' \) such that for any \( \langle C, \text{In}_C, \text{Out}_C \rangle \in T \) and \( \mathcal{F}_C \subseteq \mathcal{F} \) defined by
$C = \bigoplus_{F \in \mathcal{F}} F$ it holds that \( x \in \bigcup_{F \in \mathcal{F}} F \) for any \( x \in \text{In}_C \) and \( y \notin \bigcup_{F \in \mathcal{F}} F \) for any \( y \in \text{Out}_C \).

**Proof:** (⇒) Suppose \( \tilde{G} \) is a \( T \)-embedding of \( G \). Triangulating \( \tilde{G} \) in the plane leads to an embedding \( \tilde{G}' \) of a maximal planar and thus 3-connected graph \( G' \). The inner facial cycles of \( \tilde{G}' \) are induced non-separating cycles and form a basis \( \mathcal{F} \) of \( C(G') \). Let be \( \langle C, \text{In}_C, \text{Out}_C \rangle \in T \) and \( \mathcal{F}_C \) be the set of cycles in \( \mathcal{F} \) whose sum is \( C \). Since any edge of \( \text{In}_C \) is contained in \( \text{Int} \tilde{C} \) of \( \tilde{G} \), and thus of \( \tilde{G}' \), it belongs to some cycle in \( \mathcal{F}_C \). Analogously, any edge of \( \text{Out}_C \) is contained in \( \text{Ext} \tilde{C} \) of \( \tilde{G}' \) and therefore does not belong to some cycle of \( \mathcal{F}_C \).

(⇐) Let \( G' \) be the supergraph of \( G \) satisfying the required properties. Then there is an embedding \( \tilde{G}' \) of \( G' \) with \( \bigoplus_{F \in \mathcal{F}} F \) as the outer facial cycle and all \( F \in \mathcal{F} \) as inner facial cycles. For any \( \langle C, \text{In}_C, \text{Out}_C \rangle \in T \) we have that all edges of \( \text{In}_C \) are contained in \( \text{Int} \tilde{C} \) in \( \tilde{G}' \) and all edges of \( \text{Out}_C \) are contained in \( \text{Ext} \tilde{C} \) in \( \tilde{G}' \). Thus, we get a \( T \)-embedding \( \tilde{G} \) by restricting \( \tilde{G}' \) to \( G \).

Figure 2: Illustration of Theorem 1: (a) Graph \( G \) with constraint \( T \). (b) Supergraph \( G' \) of \( G \) with basis \( \mathcal{F} \) of \( C(G) \) and set \( \mathcal{F}_C \) of those cycles in \( \mathcal{F} \) whose sum is \( C \).

In case of 3-connected graphs, this criterion leads directly to an algorithm for finding a \( T \)-embedding. To ensure linear time complexity, we use dual graphs to represent the relationships between facial cycles (see [7]). Suppose \( G \) is a 3-connected planar graph and \( \mathcal{F} \) the unique set of facial cycles of some embedding of \( G \). Any two facial cycles have at most one edge in common and each edge belongs to exactly two facial cycles. We define the dual graph \( G^* \) on \( \mathcal{F} \) such that two facial cycles are adjacent iff they share an edge. Since edges of \( G \) are in a one-to-one correspondence to edges of \( G^* \), let \( C^* \) denote the set of edges in \( G^* \) that correspond to the edges of \( C \subseteq E(G) \). \( G^* \) has the interesting property that \( C \subseteq E(G) \) is a cycle in \( G \) iff \( C^* \) is a minimal cut in \( G^* \), i.e. removing \( C^* \) from \( G^* \) separates \( G^* \) into two components \( U^*, W^* \subseteq G^* \). These components satisfy \( C = \bigoplus_{F \in U^*} F = \bigoplus_{F \in W^*} F \). Thus, in any embedding of \( G U^* \) the
set of facial cycles inside $C$ and $W^*$ is the set of facial cycles outside $C$, or vice versa. Figure 3 illustrates the relationship between $G$ and $G^*$.

![Figure 3](image)

(a) A 3-connected planar graph $G$ with a cycle $C$ and unique faces $F_1, \ldots, F_6$. (b) The dual Graph $G^*$ of $G$ with minimal cut $C^* = \{F_1F_6, F_2F_5, F_4F_5, F_3F_6\}$ corresponding to $C$ and the sets $U^* = \{F_1, F_2, F_3, F_4\}$, $W^* = \{F_5, F_6\}$.

To find a $T$-embedding, we only have to decide for each $C$ whether $U^*$ or $W^*$ is the set of facial cycles outside $C$ and to search for a facial cycle $F_0$ belonging to each of these sets. Then $F_0$ can be chosen as the outer facial cycle. We describe the algorithm in Fig. 4 and prove its correctness in Theorem 2.

**Algorithm embed_triconnected_graph**

**Input:** $G$, $T$

**Output:** outer facial cycle $F_0$ of some $T$-embedding

1. Find the set $\mathcal{F}$ of facial cycles of some embedding of $G$.
2. Construct the dual graph $G^*$.
3. For each $\langle C, \text{In}_C, \text{Out}_C \rangle \in T$ find the components $U^*_C, W^*_C$ of $G^* - C^*$. Let be $U_C = \bigcup_{F \in U^*_C} F$ and $W_C = \bigcup_{F \in W^*_C} F$.
   - If $\text{In}_C \subset U_C$ and $\text{Out}_C \subset W_C$, define $Z^*_C = W^*_C$;
   - Else if $\text{In}_C \subset W_C$ and $\text{Out}_C \subset U_C$, define $Z^*_C = U^*_C$; else stop.
4. If there is some cycle $F_0 \in \mathcal{F}$ belonging to each $Z^*_C$, return $F_0$.

![Figure 4](image)

Figure 4: Embedding algorithm for 3-connected graphs

**Theorem 2** Given a 3-connected graph $G$ and a set $T$ of topological constraints for $G$, algorithm embed_triconnected_graph generates a $T$-embedding represented by its outer facial cycle iff $G$ is $T$-planar. Moreover, it has time complexity $O(n t)$.

**Proof:** ($\Rightarrow$) Suppose the algorithm returns some $F_0$. There is some embedding $\tilde{G}$ of $G$ with inner facial cycles $\mathcal{F}' = \mathcal{F} \setminus \{F_0\}$ and outer facial cycle $F_0$. By definition of the $Z^*_C$, we have for any $\langle C, \text{In}_C, \text{Out}_C \rangle \in T$ and $\mathcal{F}_C := \mathcal{F} \setminus Z^*_C \subseteq \mathcal{F}'$
that $\bigcup_{F \in \mathcal{F}_C} F$ contains all edges of $\text{In}_C$ but no edge of $\text{Out}_C$. Thus, by Theorem 1, $\tilde{G}$ is a T-embedding.

$(\Leftarrow)$ Conversely, assume $G$ to have a T-embedding $\tilde{G}$ with the set $\mathcal{F}'$ of inner facial cycles and outer facial cycle $F_0'$. We have to show that the algorithm always generates a cycle $F_0'$ as required. Let for any $(C, \text{In}_C, \text{Out}_C) \in T \mathcal{F}_C$ denote the sum of those cycles in $\mathcal{F}'$ that sum up to $C$. $\mathcal{F}_C$ and $(\mathcal{F}' \cup F_0') \setminus \mathcal{F}_C$ are exactly the components $U_C^*, W_C^*$ of $G^* - C^*$ and, by Theorem 1, $\bigcup_{F \in \mathcal{F}_C} F$ contains all edges of $\text{In}_C$ but no edge of $\text{Out}_C$. Thus, the algorithm defines $Z_C^*$ to be $(\mathcal{F}' \cup F_0') \setminus \mathcal{F}_C$. At least $F_0'$ belongs to each $Z_C^*$ such that the algorithm can return some cycle $F_0 \in \bigcap_C Z_C^*$.

Finally, this algorithm can be implemented as an $O(nt)$ procedure: generating the facial cycles of $G$ by embedding $G$ takes $O(n)$ time as well as the construction of the dual graph $G^*$. Since finding the components $U_C^*$ and $W_C^*$ of $G^* - C^*$ and testing the required conditions can both be done in $O(n)$ time, step 3 takes all in all $O(nt)$ time. The last step also needs only $O(nt)$ time. □

Basicly, this polynomial time T-planarity algorithm depends on the simple topological properties of 3-connected planar graphs. The next theorem shows that in the general case we cannot hope for such a polynomial time solution. This also holds for some natural restrictions of the problem.

**Theorem 3** The problem of T-planarity is NP-complete.

**Proof:** Membership in NP follows immediately from Theorem 2: we only have to guess a 3-connected planar supergraph $G'$ of $G$ and verify in polynomial time $G'$ to be T-planar.

Next we show the problem to be NP-hard by transformation from the NP-complete problem BETWEENNESS (see [13]) defined as: given a finite set $A$ and a set $S$ of ordered triples of distinct elements from $A$, is there a one-to-one function $f : A \rightarrow \{1, \ldots, |A|\}$ such that for each $(a, b, c) \in S$ either $f(a) < f(b) < f(c)$ or $f(c) < f(b) < f(a)$ holds? Let $A = \{a_1, \ldots, a_n\}$ and $S$ be an arbitrary instance of BETWEENNESS. We associate with $A$ the graph $G_A$ defined by $V(G_A) = \{x, y, a_1, \ldots, a_n\}$ and $E(G_A) = \{xa_i, ay \mid i \in \{1, \ldots, n\}\}$. For any $i, j$ with $1 \leq i < j \leq n$ let $C_{i,j}$ denote the cycle $(x, a_i, a_j, y)$ illustrated in Fig. 5. Then, $S$ is encoded by a set $T_S$ of topological constraints for $G_A$: let $\text{In}_{C_{i,j}}$ be the set $\{xa_k \mid (a_i, a_k, a_j) \in S \text{ or } (a_j, a_k, a_i) \in S\}$ and $T_S$ be the set of triples $(C_{i,j}, \text{In}_{C_{i,j}}, 0)$ with nonempty $\text{In}_{C_{i,j}}$.

We show that $G_A$ is $T_S$-planar iff there is some function $f$ satisfying the requirements given above. Suppose $\tilde{G}_A$ is a $T_S$-embedding of $G_A$ where $a'$ and $a''$ are the two vertices of $G_A$ belonging to the outer facial cycle of $\tilde{G}_A$. We define a linear order $f$ on $A$ by $f(a') = 1$, $f(a'') = n$ and inductively $f(1) = i$ if $a \neq a''$ and $a$ belongs to the outer facial cycle of $\tilde{G}_A$ where the vertices $f^{-1}(1), \ldots, f^{-1}(i-1)$ are removed. It follows immediately that for each $(a, b, c) \in S$ $f(b)$ is between $f(a)$ and $f(c)$.

Conversely, suppose $f$ has the required property. Then $G_A$ can be embedded while preserving the order of $f$, i.e. $f^{-1}(i)$ and $f^{-1}(i+1)$ belong to the same
inner facial cycle and \( f^{-1}(1) \) and \( f^{-1}(n) \) belong to the outer facial cycle. Thus, all edges of \( \text{In}_{C_{i,j}} \) are inside \( C_{i,j} \).

According to the special properties of \( G_A \) and \( T_S \) defined in the proof, we can draw some further conclusions. Since \( G_A \) is 2-connected and has treewidth 2, \( T \)-planarity remains NP-complete for the class of graphs having these properties. Thus, unlike many other graph problems, a bounded treewidth does not result in a polynomial time solution in case of \( T \)-planarity. With respect to the connectivity number \( \kappa \) of graphs, we get the exact boundary between P and NP: the problem is NP-complete for \( \kappa \leq 2 \) while allowing a polynomial time solution for \( \kappa \geq 3 \). \( T \)-planarity remains also NP-complete for Eulerian graphs since \( G_A \) is Eulerian (if \(|A|\) is odd, we have to add the edge \( xy \) to \( E(G_A) \)). Interestingly, NP-completeness holds for topological constraints of the form \( \langle C, \text{In}_C, \emptyset \rangle \). Since in the proof any \( xa_k \in \text{In}_{C_{i,j}} \) can be expressed equivalently by \( xa_i \in \text{Out}_{C_{k,j}} \) and \( xa_j \in \text{Out}_{C_{i,k}} \), this is also valid for constraints of the form \( \langle C, \emptyset, \text{Out}_C \rangle \).

4 Reduction to Biconnected Graphs

As far as classical planarity is concerned, the planarity problem of a graph can be simply reduced to its blocks. Correspondingly, many graph embedding algorithms, e.g. [3] and [18], require the input graph to be 2-connected. The embedded blocks can be easily merged to an embedding of the whole graph. A corresponding reduction for \( T \)-planarity, however, must involve all the topological constraints between the components and blocks. In this section we develop a polynomial time algorithm providing such a reduction in two steps: first, \( T \)-planarity for a graph is reduced to its components and second, connected graphs with constraints are reduced to their blocks. Thus, it is sufficient to focus on 2-connected graphs when searching for polynomial time subproblems or heuristics to cope with the general NP-complete problem.
4.1 Reducing a Graph to Its Components

Topological constraints for an arbitrary planar graph can considerably differ from those for a 2-connected graph: this is due to the fact that topological constraints between its components or blocks imply yet another sort of constraints not subsumed by Definition 1. Suppose we have two components \( H \) and \( H' \) of a graph \( G \) and three constraints meaning that \( x \in E(H') \) must be embedded inside cycles \( C_1 \) and \( C_2 \), but outside cycle \( C_3 \) of \( H \). To find an embedding of \( G \) satisfying these constraints, we have to find an embedding \( \tilde{H} \) of \( H \) with an inner face inside \( \tilde{C}_1 \) and \( \tilde{C}_2 \), but outside \( \tilde{C}_3 \) in which we can embed \( H' \). Thus, we get a new constraint between cycles of the same component that cannot be equivalently expressed by topological constraints. Although again topological by nature, we call constraints of this sort overlap constraints. More formally:

**Definition 2** Let \( G \) be a graph and \( \mathcal{L} \) be a set of pairs \( L_i = \langle C-\text{In}_i, C-\text{Out}_i \rangle \) such that \( C-\text{In}_i \) and \( C-\text{Out}_i \) are sets of cycles of \( G \). These pairs are called overlap constraints for \( G \).

An embedding \( \tilde{G} \) of \( G \) satisfies \( \mathcal{L} \) if for each constraint \( L_i \in \mathcal{L} \) there is a face of \( \tilde{G} \) in the interior of all cycles of \( C-\text{In}_i \) and in the exterior of all cycles of \( C-\text{Out}_i \); such an embedding is called an \( \mathcal{L} \)-embedding. Moreover, \( G \) is \( \mathcal{L} \)-planar if \( G \) has an \( \mathcal{L} \)-embedding.

We only consider overlap constraints that are induced by topological constraints though they might be of general interest. If a graph has an embedding satisfying both topological constraints \( T \) and overlap constraints \( \mathcal{L} \), we call it \( T \mathcal{L} \)-planar and its embedding \( T \mathcal{L} \)-embedding for short. If \( H \) is a subgraph of \( G \), we denote with \( T|_H \) the set of topological constraints which \( T \) induces on \( H \), i.e. \( \langle C_i, \text{In}_i \cap E(H), \text{Out}_i \cap E(H) \rangle \) if \( C_i \) is a cycle in \( H \) and \( \langle C_i, \text{In}_i, \text{Out}_i \rangle \in T \).

Suppose \( G \) is a planar graph, \( T \) is a set of topological constraints for \( G \) and \( \mathcal{H} \) is the set of components of \( G \) to which we want to reduce \( T \)-planarity. To represent the induced constraints between distinct components \( H, H' \in \mathcal{H} \), we define the following sets:

\[
\begin{align*}
C-\text{In}_{H,H'} &= \{ C \subset H \mid \langle C, \text{In}_C, \text{Out}_C \rangle \in T \text{ with } \text{In}_C \cap E(H') \neq \emptyset \}, \\
C-\text{Out}_{H,H'} &= \{ C \subset H \mid \langle C, \text{In}_C, \text{Out}_C \rangle \in T \text{ with } \text{Out}_C \cap E(H') \neq \emptyset \}.
\end{align*}
\]

The sets \( C-\text{In}_{H,H'} \) define moreover a relation \(< \) on \( \mathcal{H} \) by \( H' < H \) iff \( C-\text{In}_{H,H'} \neq \emptyset \). This relation means that we have to find an embedding of \( H \) that has a face inside all cycles of \( C-\text{In}_{H,H'} \) and outside all cycles of \( C-\text{Out}_{H,H'} \), thus satisfying the overlap constraint \( \langle C-\text{In}_{H,H'}, C-\text{Out}_{H,H'} \rangle \). However, there are much more overlap constraints for \( H \). Consider the set \( \mathcal{H}' \) of all successors of \( H \), i.e. \( \{ H' \mid H' \prec H \} \), and let \( K \) be a component of (the undirected graph of) \( < \) restricted to \( \mathcal{H}' \). Then all \( H' \in K \) must lie in the same face of an embedding of \( H \). The stronger overlap constraints for \( H \) are thus \( \bigcup_{H' \in K} C-\text{In}_{H,H'} \cup C-\text{Out}_{H,H'} \) for all such \( K \).

Now consider an embedding \( \tilde{G} \) of \( G \) and the induced ordering \(< \) on \( \mathcal{H} \) by \( H' < H \) iff \( \tilde{G}|_{H'} \) is in some inner face of \( \tilde{G}|_H \). It can be easily seen, that \(< \) is
a strict partial order with the additional property that $H' < H$ and $H' < H''$ imply either $H < H''$ or $H = H''$ or $H'' < H$ due to planarity. In other words, $<$ is the transitive closure of a disjoint union of rooted trees. If moreover $\tilde{G}$ is a $T$-embedding, the relation $\prec$ defined above is a subrelation of $<$. An example of both relations is given in Fig. 6.\(^2\)

Figure 6: (a) A graph $G$ consisting of components $H_1, \ldots, H_4$ and topological constraints between them represented by the sets $C\text{-In}_{H_i,H_j}$ and $C\text{-Out}_{H_i,H_j}$; these sets define the relation $\prec$. (b) An embedding $\tilde{G}$ satisfying these constraints and the relation $<\,$ induced by $\tilde{G}$.

The method of reducing $T$-planarity of $G$ to its components consists just in finding such an extention $<\,$ of $\prec$ and appropriate embeddings of the components of $G$. Instead of the strict partial ordering $<\,$, it is more convenient to construct its transitive reduction which is a disjoint union of rooted trees. When first considering subsets $\mathcal{H}' \subset \mathcal{H}$ such that $\prec |_{\mathcal{H}'}$ is a connected relation, we can easily formulate a recursive procedure $\text{order\_components}$ shown in Fig. 7 for constructing the transitive reduction of $<\,$ w.r.t. to $\mathcal{H}'$. It makes use of an algorithm $A$ for generating an embedding of a connected graph satisfying given topological and overlap constraints; we also assume that the faces corresponding to the overlap constraints are returned. Such an algorithm $A$ is provided by the reduction to blocks developed in the next section. The procedure $\text{order\_components}$ returns a tree of embedded components in $\mathcal{H}'$ where an edge from $\tilde{H}$ to $\tilde{H}'$ is labelled with a face of $H$ in which $\tilde{H}'$ must be embedded. Figure 8 shows the only two possible labelled trees that can result from the graph and constraints given in

\(^2\)Note that we visualize relations like $\prec$ by drawing an arrow from $H$ to $H'$ if $H' \prec H$. 
Fig. 6 (a). Here we have labelled an edge from $\tilde{H}$ to $\tilde{H}'$ by the overlap constraint for $\tilde{H}$ instead of its corresponding face. The first labelled tree corresponds to the embedding shown in Fig. 6 (b).

Algorithm order components

Input: $\mathcal{H}' \subset \mathcal{H}$ such that $\prec |_{\mathcal{H}'}$ is connected

Output: labelled tree of embedded components of $\mathcal{H}'$

1. Determine the set $M$ of components maximal in $\prec |_{\mathcal{H}'}$.
2. Use algorithm $A$ to find an $H \in M$ with an embedding $\tilde{H}$ satisfying $T_H$ and set $L_H$ of constraints $L_i = \langle \bigcup_{H' \in K_i} C$-In$_{H,H'}, \bigcup_{H' \in K_i} C$-Out$_{H,H'} \rangle$ for components $K_i$ of $\prec |_{\mathcal{H}' \setminus \{H\}}$.
   
   If this succeeds, let $F_i$ be the faces of $\tilde{H}$ corresponding to $L_i$, else stop.
3. For all $K_i$ compute order components($K_i$) resulting in labelled trees $R_i$.
4. Merge the $R_i$ to a new tree with root $\tilde{H}$ by adding edges from $\tilde{H}$ to the roots of $R_i$ labelled with $F_i$. Finally, return this new tree.

Figure 7: Algorithm for ordering components

Figure 8: Two labelled trees that can result from procedure order components for the graph and constraints given in Fig. 6. Instead of faces, the edges are labelled with the corresponding overlap constraints.

The complete reduction algorithm reduce to components is given in Fig. 9. To obtain a $T$-embedding of $G$, we only have to embed the components of $G$ according to the structure of the generated trees. Finally, we prove correctness and the time complexity for this algorithm in Theorem 4. We therefore assume that an algorithm $A$ is available for embedding a component $H$ with topological constraints $T_H$ and overlap constraints $L_H$. Its time complexity is assumed to be $O(p(n_H, k_H, t_H, l_H))$ for some polynomial $p$ with parameters $n_H = |H|$, $t_H = |T_H|$, $l_H = |L_H|$ and the number $k_H$ of all cycles occurring in the constraints of $T_H$ and $L_H$. Note that each overlap constraint consists then of at most $k_H$ cycles.

Theorem 4 Let $G$ be a planar graph and $T$ be a set of topological constraints for $G$. Then, algorithm reduce to components generates a $T$-embedding of $G$ iff
Algorithm reduce_to_components

Input: G, T
Output: T-embedding of G

1. Determine the set \( H \) of components of \( G \).
2. Determine the sets C-\( \text{In}_{H,H'} \) and C-\( \text{Out}_{H,H'} \), the induced constraints \( T_H := T|_H \) and the relation \( \prec \). If \( \prec \) is cyclic, stop.
3. For each component \( K_i \) of \( \prec \) compute order_components\( (K_i) \) resulting in labelled trees \( R_i \).
4. Construct the embedding of \( G \) as described by the \( R_i \), i.e. embed \( \tilde{H}' \) into face \( F \) of \( \tilde{H} \) iff there is an edge from \( \tilde{H} \) to \( \tilde{H}' \) labelled with \( F \).

Figure 9: Reduction of T-planarity of a graph to its components

\( G \) is T-planar. Moreover, it takes \( O(n^4 + n^2 t + n \cdot p(n,t,t,n)) \) time provided that the time complexity of \( A \) is given by \( p \).

Proof: \((\Rightarrow)\) Suppose \( \tilde{G} \) is an embedding of \( G \) generated by the algorithm and \( \prec \) is the induced relation on \( H \). We have to show that \( \tilde{G} \) is indeed a T-embedding. Let be \( (C, \text{In}_C, \text{Out}_C) \in \mathcal{T} \) and \( \tilde{H} \) be the generated embedding of the component \( H \in \mathcal{H} \) with \( C \subset H \).

First, consider an \( x \in \text{In}_C \) belonging to component \( H' \in \mathcal{H} \). If \( H = H' \), \( x \) is inside \( C \) in \( \tilde{H} \) since \( \tilde{H} \) is a \( T_H \)-embedding. Otherwise we have \( H' \prec H \). When choosing \( H \) for embedding in step 2 of algorithm order_components, \( H' \) belongs to some component \( K_i \) of \( \prec \mid_{H'} \). Thus, the overlap constraint \( L_i \) ensures that all \( H' \in K_i \) are embedded in a face inside \( \tilde{C} \) of \( \tilde{H} \).

Second, consider an \( x \in \text{Out}_C \) belonging to component \( H' \in \mathcal{H} \). Again, if \( H = H' \), \( x \) is outside \( C \) in \( \tilde{H} \) since \( \tilde{H} \) is a \( T_H \)-embedding. Otherwise we have \( C \in \text{C-\text{Out}}_{H,H'} \). If \( H' \prec H \) holds in \( \tilde{G} \), \( H' \) must be in some component \( K_i \) of \( \prec \mid_{H' \setminus \{H\}} \) determined in step 2 of algorithm order_components. Thus, the overlap constraint \( L_i \) ensures that all \( H' \in K_i \) are embedded in a face outside \( C \) of \( \tilde{H} \). If \( H' \prec H \) does not hold in \( \tilde{G} \), \( H' \) is obviously outside \( C \) of \( \tilde{G} \).

\((\Leftarrow)\) Conversely, we show that the algorithm indeed finds an embedding of \( G \) if \( G \) is T-planar. By the first part of the proof, such an embedding always satisfies \( T \). So let \( \tilde{G} \) be a T-embedding of \( G \) and \( \prec \) be its induced relation on \( H \). Since \( \prec \) is an extention of \( \prec \), \( \prec \) is in particular acyclic. For a connected subrelation \( \prec \mid_{H'} \) of \( \prec \) we denote with \( \tilde{G}'|_{H'} \) the restriction of some T-embedding \( \tilde{G}' \) of \( G \) to the components in \( H' \). Note that each \( \tilde{G}'|_{H'} \) has a unique maximal component in \( \prec \mid_{H'} \).

We must show that for each call of procedure order_components the search for an appropriate maximal component \( H \) always succeeds. For this purpose we define inductively a T-embedding \( \tilde{G}'|_{H'} \) for each call order_components\( (H') \) such that the maximal component of \( \tilde{G}'|_{H'} \) is a possible choice in step 2. Let \( K_i \) be the components of \( \prec \) and let \( \tilde{G}' \) be the embedding of \( G \) built by placing
all $\tilde{G}|_{K_i}$ into different regions of the plane. Obviously, $\tilde{G}$ satisfies $T$ again. We define each $\tilde{G}_{K_i}$ to be $\tilde{G}^{'}$. Thus, for each call $\text{order\_components}(K_i)$ the maximal component of $\tilde{G}_{K_i}|_{K_i}$ is a possible choice for $H$ in step 2.

Consider now some call $\text{order\_components}(H')$ and let $\tilde{G}_{H'}$ be already defined. By assumption, the search in step 2 for an $H \in H'$ succeeds; however, $H$ is not necessarily identical with the maximal component of $\tilde{G}_{H'}|_{H'}$. Let $K_i$ be the components of $\prec |_{H'}\setminus \{H\}$ and $F_i$ be the corresponding faces of the generated embedding $\tilde{H}$ in which the components in $K_i$ must be embedded. Transform $G_{H'}$ into a new embedding $\tilde{G}'$ of $G$ by replacing $G_{H'}|_{H}$ with $\tilde{H}$ and placing each $\tilde{G}_{H'}|_{K_i}$ into the face $F_i$ of $\tilde{H}$. Again, $\tilde{G}'$ satisfies $T$. We define each $\tilde{G}_{K_i}$ to be $\tilde{G}'$. Consequently, for each call $\text{order\_components}(K_i)$ the maximal component of $\tilde{G}_{K_i}|_{K_i}$ is a possible choice for $H$ in step 2. This completes the proof that the algorithm never stops irregularly if $G$ is $T$-planar.

Finally, we derive the time complexity of $\text{reduce\_to\_components}$ from algorithm $A$. As can be easily seen, step 1, 2 and 4 of $\text{reduce\_to\_components}$ takes $O(n), O(nt) + O(n^2)$ and $O(n)$ time, respectively. To establish the time needed by step 3, we consider the call $\text{order\_components}(H')$ for some $H' \subset H$. First, the set $M$ of maximal components of $\prec |_{H'}$ can be determined in $O(n)$ time.

For some $H_j \in M$ let be $n_j = |H_j|$, $t_j = |T_{H_j}|$, $l_j = |L_{H_j}|$ and $k_j$ be the number of cycles occurring in $T_{H_j}$ and $L_{H_j}$, i.e. the number of cycles in $H_j$ occurring in $T$. Then, computing the $l_j$ components of $\prec |_{H'\setminus \{H\}}$ can be done in $O(n^2)$ time and determining the constraints $L_{H_j}$ needs $O(nk_j)$ time. By assumption, testing if $H_j$ is $T_{H_j}, L_{H_j}$-planar can be done in $O(p(n_j, k_j, t_j, l_j))$ time. In the worst case, however, all the $H_j \in M$ must be checked. It is clear that $\sum n_j = n$, $\sum k_j = t$ and $\sum t_j \leq t$. Additionally, we have $\sum t_j \leq 2n$ since $\sum l_j$ is largest if $\prec |_{H'}$ is a tree and for a tree the sum is twice the number of edges. Thus, step 2 of $\text{order\_components}$ can be done in

$$\sum (O(n^2) + O(nk_j) + O(p(n_j, k_j, t_j, l_j)))$$

$$= O \left( \sum n^2 + \sum nk_j + p \left( \sum n_j, \sum k_j, \sum t_j, \sum l_j \right) \right)$$

$$= O \left( n^3 + nt + p(n, t, t, n) \right).$$

Since the number of calls of $\text{order\_components}$ is bounded by $n$, we get the overall complexity $O\left(n^4 + n^2t + n \cdot p(n, t, t, n)\right)$ for algorithm $\text{reduce\_to\_components}$. \hfill $\square$

### 4.2 Reducing a Component to Its Blocks

The second part of reducing $T$-planarity of a graph $G$ consists of reducing its components $H$ with induced topological constraints $T_H$ and overlap constraints $L_H$ to its blocks. Again, this reduction step leads to a new sort of constraints between blocks which are similar, but not entirely equivalent with overlap constraints. Consider two blocks $B$ and $B'$ of $H$ having a cutvertex $v$ in common and suppose we have constraints in $T_H$ meaning that $B'$ must be embedded inside cycles $C_1$ and $C_2$, but outside cycle $C_3$ of $B$. A corresponding embedding
of $B$ must clearly satisfy the overlap constraint $\langle \{C_1, C_2\}, C_3 \rangle$. However, due to the way these blocks are connected to each other, the topological constraints imply additional requirements: first, the boundary of the face in $B$ inside $C_1$ and $C_2$, but outside $C_3$ must contain the cutvertex $v$, and second, $v$ must belong to the boundary of the outer face of the embedding $\tilde{B}'$ of $B'$ in order to merge $B$ and $B'$ to an embedding of $B \cup B'$ satisfying the constraints given above. Since these constraints are an extension of overlap constraints, we call them extended overlap constraints.

**Definition 3** Let $G$ be a graph and $\mathcal{X}$ be a set of triples $X_i = \langle C-\text{In}_i, C-\text{Out}_i, v \rangle$ such that $C-\text{In}_i$ and $C-\text{Out}_i$ are sets of cycles of $G$ and $v$ is a vertex of $G$. These triples are called extended overlap constraints for $G$.

An embedding $\tilde{G}$ of $G$ satisfies $\mathcal{X}$ if for each constraint $X_i \in \mathcal{X}$ there is a face of $\tilde{G}$ in the interior of all cycles of $C-\text{In}_i$ and in the exterior of all cycles of $C-\text{Out}_i$, and whose boundary contains $v$; such an embedding is called an $\mathcal{X}$-embedding. Moreover, $G$ is $\mathcal{X}$-planar if $G$ has an $\mathcal{X}$-embedding.

We are again only interested in those extended overlap constraints that are derived in the reduction step. It can easily be seen that the requirement for $B'$ to have $v$ at the boundary of the outer face can be expressed by the extended overlap constraint $\langle \emptyset, C-\text{Out}, v \rangle$ where $C-\text{Out}$ denotes the set of all cycles occurring in the constraints for $B'$. This is because taking the face corresponding to this extended overlap constraint as the outer face results in the required embedding where $v$ is on the outer face boundary and all other constraints are preserved.

The reduction of $T_H\mathcal{L}_H$-planarity of $H$ to its blocks works much like the first reduction step of $G$ to its components. This is due to the fact that any embedding of $H$ induces again an ordering $<$ on the set $\mathcal{B}$ of blocks of $H$ with the same properties as defined in the previous section. Thus we can adopt the key idea of constructing an appropriate ordering of the blocks. However, some minor modifications are necessary to cope with both the overlap constraints $\mathcal{L}_H$ and the extended overlap constraints derived during the reduction process. We use the block graph $H_b$ of $H$, as defined in Sect. 1, to represent the complete decomposition of $H$ into its blocks and cutvertices. Note that $H_b$ is a tree because $H$ is connected.

Analogously to the previous section, we represent the constraints between distinct blocks $B, B' \in \mathcal{B}$ by the sets $\text{C-In}_{B,B'}$ and $\text{C-Out}_{B,B'}$. By defining them in terms of $C$-components, many constraints between $B$ and further blocks are inferred. For the sake of a uniform representation, we transform the overlap constraints $L_i \in \mathcal{L}_H$ into the sets $\text{C-In}_{B,L_i}$ and $\text{C-Out}_{B,L_i}$.

\[
\begin{align*}
\text{C-In}_{B,B'} & = \{ C \subset B \mid \langle C, \text{In}_C, \text{Out}_C \rangle \in T_H \text{ with } \text{In}_C \cap \text{E}(Z) \neq \emptyset \text{ for some } C\text{-component } Z \text{ containing } B' \}, \\
\text{C-Out}_{B,B'} & = \{ C \subset B \mid \langle C, \text{In}_C, \text{Out}_C \rangle \in T_H \text{ with } \text{Out}_C \cap \text{E}(Z) \neq \emptyset \text{ for some } C\text{-component } Z \text{ containing } B' \}, \\
\text{C-In}_{B,L_i} & = \{ C \subset B \mid L_i = \langle \text{C-In}_i, \text{C-Out}_i \rangle \in \mathcal{L}_H \text{ with } C \in \text{C-In}_i \}, \\
\text{C-Out}_{B,L_i} & = \{ C \subset B \mid L_i = \langle \text{C-In}_i, \text{C-Out}_i \rangle \in \mathcal{L}_H \text{ with } C \in \text{C-Out}_i \}.
\end{align*}
\]
The sets $\text{C-In}_{B,B'}$ and $\text{C-In}_{B,L_i}$ define again a relation $\prec$ on $B \cup L_H$ by $B' \prec B$ iff $\text{C-In}_{B,B'} \neq \emptyset$ and $L_i \prec B$ iff $\text{C-In}_{B,L_i} \neq \emptyset$. The reason for including the constraints of $L_H$ is that this ensures all blocks $B$ with $L_i \prec B$ to be embedded in a linear order of $\prec$ as must be the case in any embedding of $H$ satisfying $L_H$ (see for example Fig. 12).

The algorithm $\text{reduce_to_blocks}$ providing the second reduction step is presented in Fig. 10. Again, the resulting embedding of $H$ is obtained from a labelled tree that is generated by the procedure $\text{order_blocks}$ given in Fig. 11.

This procedure assumes that some block $B_0$ is selected from those blocks that are maximal in $\prec$ to serve as a maximal block in the relation $\prec$ induced by the $T_HL_H$-embedding of $H$ to be generated. Thus, contrary to the reduction algorithm in the previous section, finding a $T_HL_H$-embedding of $H$ possibly requires several complete reduction processes if necessary until a proper $B_0$ leads to the required embedding. This is due to the fact that the generated extended overlap constraints for the blocks are partially depending on the choice of $B_0$; for instance, all other blocks $B$ with cutvertex $q$ in the path $B_0, \ldots, q, B$ of $H_b$ are to be embedded with $q$ at the outer face boundary. Instead of relation $\prec$, procedure $\text{order_blocks}$ uses for technical reasons an extension $\prec'$ of $\prec$ by adding $B' \prec' B$ iff $B_0, \ldots, B, q, B'$ is a path in $H_b$. This enforces the search of which block to consider next in step 2 of $\text{order_blocks}$ to take those blocks that are nearest to $B_0$ in the tree $H_b$. Note that in general, however, $\prec'$ is no longer a subrelation of $\prec$ induced by some $T_HL_H$-embedding of $H$. Algorithm $\text{order_blocks}$ works similarly to its corresponding procedure $\text{order_components}$ except for those parts where the block graph must be taken into account.

**Algorithm $\text{reduce_to_blocks}$**

*Input*: component $H$ with constraints $T_H$ and $L_H$

*Output*: $T_HL_H$-embedding of $H$

1. Determine the set $B$ of blocks of $H$ and the blockgraph $H_b$ of $H$.
2. Determine the sets $\text{C-In}_{B,B'}$, $\text{C-Out}_{B,B'}$, $\text{C-In}_{B,L_i}$, and $\text{C-Out}_{B,L_i}$, the constraints $T_B := T_H|_B$ and the relation $\prec$. If $\prec$ is cyclic, stop.
3. Find a block $B_0$ maximal in $\prec$ such that $\text{order_blocks}(B \cup L_H)$ results in a labelled tree $R$ using the extension $\prec'$ of $\prec$ by $B' \prec' B$ iff $B_0, \ldots, B, q, B'$ is a path in $H_b$. If this fails, stop.
4. Construct the embedding of $H$ as described by $R$, i.e. for any edge from $\tilde{B}$ to $\tilde{B'}$ labelled with $F$ and for the cutvertex $p$ with path $B, p, B'$ in $H_b$ embed $\tilde{B'}$ into face $F$ at $p$ of $\tilde{B}$. Additionally, return the faces corresponding to the overlap constraints $L_i \in L_H$, i.e. the labels of the edges to $L_i$ in $R$.

Figure 10: Reduction of $T_HL_H$-planarity of a connected graph to its blocks

Figure 12 illustrates this reduction step with a simple connected graph $H$ whose blocks $B_1, \ldots, B_4$ are cycles $C_1, \ldots, C_4$, respectively, and $B_5$ is a bridge.
The topological constraints and the overlap constraint \( L \) for \( H \) are directly encoded in the relation \( \prec \). As can easily be seen, the only correct choice for \( B_0 \) among the candidates \( B_1 \) and \( B_3 \) is \( B_0 = B_1 \). This is because \( B_0 = B_3 \) is separated in \( H_b \) by two cutvertices from \( B_2 = C_2 \) and \( B_4 = C_4 \) which inhibits embedding one of these cycles into the other and thus contradicts the overlap constraint \( L \).

To establish in Theorem 5 correctness and time complexity of algorithm reduce_to_blocks, we assume an algorithm \( A' \) to be available for embedding a block \( B \) with topological constraints \( T_B \), overlap constraints \( L_B \) and extended overlap constraints \( X_B \). The time complexity of \( A' \) is assumed to be \( O(p'(n_B,k_B,t_B,l_B,x_B)) \) for some polynomial \( p' \) with parameters \( n_B = |B|, t_B = |T_B|, l_B = |L_B|, x_B = |X_B| \) and the number \( k_B \) of all cycles occurring in the constraints of \( T_B, L_B \) and \( X_B \). Consequently, each overlap constraint and each extended overlap constraint consists of at most \( k_B \) cycles.

**Theorem 5** Let \( H \) be a connected planar graph and \( T_H \) be a set of topological constraints and \( L_H \) be a set of overlap constraints for \( H \). Then, algorithm reduce_to_blocks generates a \( T_H L_H \)-embedding of \( H \) iff \( H \) is \( T_H L_H \)-planar. Moreover, it takes \( O(n^2 + n^2 t + n^2 k + n^2 kl + nt + n^2 \cdot p'(n,k,t,l,n + l)) \) time provided that the time complexity of \( A' \) is given by \( p' \) and \( n = |H|, t = |T_H|, \)
Figure 12: (a) A connected graph $H$ with its block graph $H_b$ and the relation $\prec$ determined by $\text{C-In}_{B_1,B_2} = \{C_1\}$, $\text{C-In}_{B_3,B_4} = \{C_3\}$, $\text{C-In}_{B_2,L} = \{C_2\}$ and $\text{C-In}_{B_4,L} = \{C_4\}$. (b) The relation $\prec'$, the labelled tree $R$ and its corresponding embedding $\tilde{H}$ when $B_1$ is chosen as $B_0$.

$l = |\mathcal{L}_H|$ and $k$ is the number of all cycles occurring in the constraints of $T_H$ and $\mathcal{L}_H$.

**Proof:** ($\Rightarrow$) Suppose $\tilde{H}$ is an embedding of $H$ generated by the algorithm and $\prec$ is the induced relation on $B$. We have to show that $\tilde{H}$ is indeed a $T_H \mathcal{L}_H$-embedding. Analogously to the proof of Theorem 4, it can easily be seen that the induced topological constraints $T_B$ and the extended overlap constraints $X_i$ produced in step 2 of algorithm order_blocks guarantee that $\tilde{H}$ satisfies $T_H$.

To show that $\tilde{H}$ also satisfies $\mathcal{L}_H$, we consider an overlap constraint $L = \langle \text{C-In}, \text{C-Out} \rangle \in \mathcal{L}_H$. Suppose $F$ is the face in $\tilde{H}$ corresponding to $L$ and $B_F$ is the block with an edge to $L$ labelled with $F$ in the tree $R$ resulting from step 3 of reduce_to_blocks. That is, $B_F$ appears as the minimal block in $\prec$ containing cycles from $\text{C-In}$. When choosing $B_F$ for embedding in step 2 of order_blocks, the generated overlap constraint $L_i = \langle \text{C-In}_{B_F,K_i}, \text{C-Out}_{B_F,K_i} \rangle$ for $K_i = L$ clearly ensures that $F$ is a face inside all cycles of $\text{C-In}$ in $B_F$ and outside all cycles of $\text{C-Out}$ in $B_F$. Let $C \in \text{C-In}$ belong to some block $B \neq B_F$. Since $L$ and
$B_F$ belong to the same component $K_i$ determined in step 2 of order blocks, the face of $\tilde{B}$ corresponding to the extended overlap constraint $X_i$ is guaranteed to be inside $C$. Thus, $B_F$ is embedded inside $C$. Next, consider some $C \in \text{C-Out}$ belonging to a block $B \neq B_F$. If $B_F < B$ holds in $\tilde{H}$, $B_F$ must be in a component $K_i$. Then, the constraint $X_i$ ensures again its corresponding face in $\tilde{B}$ to be outside $C$. Otherwise, $B_F$ is obviously outside $C$ in $\tilde{H}$.

($\Leftarrow$) Conversely, we show that the algorithm never stops irregularly if $H$ is $T_H \mathcal{L}_H$-planar. Suppose $\tilde{H}$ is an embedding of $H$ satisfying the constraints $T_H$ and $\mathcal{L}_H$ and $\prec$ is the induced relation on $\mathcal{B}$. Clearly, the restriction of $\prec$ to $\mathcal{B}$ is a subrelation of $\prec$; thus $\prec$ must be acyclic. Since in step 3 of reduce_to_blocks possibly all maximal blocks in $\prec$ are considered, it is sufficient to show that the choice of a block $B_0$ which is maximal in $\prec$ succeeds. So let $\prec'$ be the extention of $\prec$ defined in step 3 which is also acyclic. In analogy to the proof of Theorem 4 we define a $T_H \mathcal{L}_H$-embedding $\tilde{H}_{B'}$ for each call order_blocks($B'$) such that the maximal component of $\tilde{H}_{B'}|_{|B|}$ is a possible choice in step 2.

First we define $\tilde{H}_{B',\mathcal{L}_H} := \tilde{H}$ such that for the call order_blocks($\mathcal{B} \cup \mathcal{L}_H$) $B_0$ is an appropriate choice in step 2; moreover, $B_0$ is the only candidate because it is the unique maximal block in $\prec'$. Consider now some call order_blocks($B'$) and let $\tilde{H}_{B'}$ be already defined. By assumption, the search in step 2 for some $B \in B'$ succeeds; however, $B$ is not necessarily identical with the maximal block of $\tilde{H}_{B'}|_{|B|}$. Let $K_i$ be the components of $\prec'|_{|B\setminus\{B\}}$ and $F_i$ be the corresponding faces of the generated embedding $\tilde{B}$ in which the blocks in $K_i$ must be embedded. Moreover, let $p_i \in B$ be the cutvertex in $H_b$ separating $B$ from $K_i$. Then transform $\tilde{H}_{B'}$ into a new embedding $H'$ of $H$ by replacing $\tilde{H}_{B'}|_{|B}$ with $B$ and placing each $\tilde{H}_{B'}|_{K_i}$ into face $F_i$ of $\tilde{B}$ at cutvertex $p_i$. Again, $H'$ satisfies $T_H$ and $\mathcal{L}_H$. When each $\tilde{H}_{K_i}$ is defined to be $\tilde{H}'$, we assure that for each call order_blocks($K_i$) the maximal block of $\tilde{H}_{K_i}|_{|K_i}$ is a possible choice in step 2. This completes the proof that this algorithm never stops irregularly if $H$ is $T_H \mathcal{L}_H$-planar.

Finally, we derive the time complexity of reduce_to_blocks from algorithm $A'$.

As can be easily seen, step 1 and 4 of reduce_to_blocks takes $O(n)$ and $O(n + l)$ time, respectively. The construction of the sets $\text{C-In}_{B,B'}$ and $\text{C-Out}_{B,B'}$ in step 2 depends on the $C$-components which can be determined in $O(nt)$ time. Then the four sets can be determined in $O(nt) + O(kl)$ time. Moreover, defining the sets $T_B$ can be done in $O(nt)$ time and the relation $\prec$ can be computed and checked in $O(n^2 + nl)$ time.

We consider next the call order_blocks($\mathcal{B}'$) for some $\mathcal{B}' \subset \mathcal{B} \cup \mathcal{L}_H$. The set $M$ of maximal components in $\prec'|_{|\mathcal{B}'}$ can be determined in $O(n)$ time. For some $B_j \in M$ let be $n_j = |B_j|$, $t_j = |T_{B_j}|$, $l_j = |\mathcal{L}_{B_j}|$, $x_j = |\mathcal{X}_{B_j}|$ and $k_j$ be the number of all cycles occurring in $T_{B_j}$, $\mathcal{L}_{B_j}$ and $\mathcal{X}_{B_j}$, i.e. the number of all cycles in $B_j$ occurring in $T_H$ and $\mathcal{L}_H$. Then, determining the $l_j + x_j$ components $K_i$ of $\prec'|_{|\mathcal{B}'\setminus\{B_j\}}$ needs $O(n^2 + nl)$ time and determining the cutvertices $p_i$ needs $O(n)$ time. Moreover, the constraints $\mathcal{X}_{B_j}$ can be found in $O((n + l)k_j)$ time whereas the constraints $\mathcal{L}_{B_j}$ consists of sets already generated. By assumption, a $T_{B_j} \mathcal{L}_{B_j} \mathcal{X}_{B_j}$-embedding, if any, can be found in $O(p'(n_j, k_j, t_j, l_j, x_j))$ time.
In the worst case, however, all the $B_i \in M$ must be checked. It is clear that $\sum n_j \leq 2n$, $\sum k_j = k$, $\sum t_j \leq t$ and $\sum l_j = l$. By the argument given in the proof of Theorem 4, we additionally get $\sum x_j \leq 2(n + l)$. Thus step 2 of order_blocks can be done in

$$\sum (O(n^2 + nl) + O((n + l)k_j) + O(p'(n_j, k_j, t_j, l_j, x_j)))$$

$$= O \left( \sum (n^2 + nl) + \sum (n + l)k_j + p' \left( \sum n_j, \sum k_j, \sum t_j, \sum l_j, \sum x_j \right) \right)$$

$$= O(n^3 + n^2l + nk + kl + p'(n, k, t, l, n + l)).$$

Since for a fixed $B_0$ the number of calls is bounded by $n$, the time needed by the call order_blocks($B \cup L_H$) in step 3 of algorithm reduce_to_blocks can be estimated by $n \left( O(n) + O(n^3 + n^2l + nk + kl + p'(n, k, t, l, n + l)) \right)$, that is $O \left( n^4 + n^3l + n^2k + nk + n \cdot p'(n, k, t, l, n + l) \right)$. In the worst case, however, all maximal blocks $B_0$ in $\prec$ must be checked. Thus we finally obtain the overall complexity

$$O \left( nt + kl + n^2 + nl \right) + n \left( O\left(n^4 + n^3l + n^2k + nk + n \cdot p'(n, k, t, l, n + l)\right) \right)$$

$$= O\left(n^5 + n^4t + n^3k + n^2kl + nt + n^2 \cdot p'(n, k, t, l, n + l)\right).$$

As an immediate consequence, we get the complexity of this algorithm when only topological constraints $T_H$ are given. In this case we have $l = 0$ and $k = t = |T_H|$. Moreover, the reduction to blocks leads only to extended overlap constraints, but not to overlap constraints.

**Corollary 1** For a connected planar graph $H$ with $n = |H|$ and a set $T_H$ of topological constraints for $H$ with $t = |T_H|$, the algorithm reduce_to_blocks takes $O \left( n^5 + n^4t + n^3 \cdot p'(n, t, t, 0, n) \right)$ time.

The combination of the algorithms developed in this and the previous section leads to the complete reduction method of $T$-planarity of a graph $G$ to its blocks. When replacing algorithm $A$ with algorithm reduce_to_blocks in Theorem 4 (and matching the corresponding parameters), the following time complexity of the complete reduction can easily be verified.

**Corollary 2** Suppose $G$ is a planar graph with $n = |G|$ and $T$ is a set of topological constraints for $G$ with $t = |T|$. Then, algorithm reduce_to_blocks combined with algorithm reduce_to_blocks takes $O \left( n^6 + n^4t + n^3 \cdot p'(n, t, t, n, 2n) \right)$ time provided that the time complexity of $A'$ is given by $p'$. We finally note that extended overlap constraints can often be simplified in the following way. Consider some constraint $X_i = \langle C_{\text{In}_i}, C_{\text{Out}_i}, v \rangle$ and a cycle $C \in C_{\text{In}_i}$. In case of $v \notin C$ we can remove $C$ from $C_{\text{In}_i}$ and create the topological constraint meaning that $v$ is to be embedded inside $C$ instead. If this constraint is satisfied, any face with $v$ at its boundary is certainly in the interior of $C$. The cycles of $C_{\text{Out}_i}$ containing $v$ can be treated analogously. Thus, this simplification results in extended overlap constraints whose vertex is contained in all cycles involved.
5 Restricted Topological Constraints

The NP-completeness result of planarity with topological constraints opens the search for interesting tractable subproblems. Such subproblems can be defined in terms of various restrictions on graphs or constraints. For instance, one can study the effect of restricting the degree of graphs to the time complexity of $T$-planarity. Instead of graph parameters, we are concerned in this section with a particular parameter inherent to topological constraints which we call cycle intersection order.

Definition 4 Given a graph $G$ and a set $C$ of cycles in $G$, the maximum number of vertices two distinct cycles of $C$ have in common is called the cycle intersection order of $C$.

For a set $T$ of topological constraints for $G$ we denote the set of cycles occurring in $T$ by $C_T$. The cycle intersection order of $T$ is the cycle intersection order of $C_T$. If $d$ is the cycle intersection order of $T$, we also write $T_d$ for $T$.

In other words, the cycle intersection order of $T$ is the maximum order of all graphs $C_i \cap C_j$ for distinct $C_i, C_j \in C_T$. We consider it a natural parameter of topological constraints since it captures an important aspect of the relationships between cycles of $C_T$ which is worth studying. In particular, we are interested in finding the exact boundary between P and NP w.r.t. this parameter.

Recalling the proof of Theorem 3, we can immediately conclude that $T_d$-planarity remains NP-hard for all $d \geq 3$. This is because any two distinct cycles involved in the defined constraints share either 2 or 3 vertices. By a minor modification of encoding a BETWEENNESS instance, we obtain NP-hardness even for $d \geq 2$.

Theorem 6 The problem of $T_d$-planarity is NP-complete for all $d \geq 2$.

Proof: It is sufficient to show NP-hardness of $T_d$-planarity for $d = 2$. Consider an instance of BETWEENNESS, i.e. a set $A = \{a_1, \ldots, a_n\}$ and a set $S = \{s_1, \ldots, s_r\}$ of ordered triples $s_j = (a_{j1}, a_{j2}, a_{j3})$ of distinct elements of $A$. We transform the graph $G_A$ defined in the proof of Theorem 3 into a graph $G'_A$ by replacing each vertex $a_i$ by the path $a_{i1}, \ldots, a_{ir}$ (with an edge from each of these vertices to $x$ and $y$) and adding some cycle $C$ which meets all these vertices involved exactly in $x$ and $y$. This construction is illustrated in Fig. 13.

For any $s_j = (a_{j1}, a_{j2}, a_{j3})$ let $C'_{j1,j3}$ denote the cycle $(x, a_{j1,j}, y, a_{j3,j}, x)$. We define $T'_S$ to contain the constraints $\langle C'_{j1,j3}, \{xa_{j2,j}\}, \emptyset \rangle$ for all triples $s_j$ and, additionally, the constraint $\langle C, \{xa_{i,j} \mid 1 \leq i \leq n, 1 \leq j \leq r\}, \emptyset \rangle$. This last constraint ensures any embedding of $G'_A$ to induce some linear order of the paths $a_{i1}, \ldots, a_{ir}$. Obviously, all these cycles have exactly $x$ and $y$ in common such that the cycle intersection order of $T'_S$ is 2. Then it can be proved analogously to Theorem 3 that $G'_A$ is $T'_S$-planar iff $(A, S)$ is a positive instance; however, we omit the details. □
Interestingly, the remaining problem of $T_1$-planarity turns out to have a positive solution. The next sections are devoted to the development of a polynomial time algorithm for generating a $T_1$-embedding. Thus, the boundary of $T_d$-planarity between P and NP will be proved to be $d = 1$. Due to the polynomial time reduction method presented in the previous section, it is sufficient to find a polynomial time embedding algorithm for 2-connected graphs and constraints that are derived from topological constraints with cycle intersection order 1. Expectedly, such an algorithm depends primarily on certain structural properties of sets of cycles in a 2-connected graph with cycle intersection order 1. The next section explores these properties as far as required for developing the $T_1$-embedding algorithm.

5.1 Decomposition of Biconnected Graphs by Cycles of Intersection Order 1

Suppose we are given a nonempty set $C$ of cycles in a planar 2-connected graph $G$ such that $C$ has cycle intersection order 1. Moreover, let $n$ denote $|G|$ and $k$ denote $|C|$. Since any edge of $G$ belongs to at most one cycle of $C$ and each cycle consists of at least three edges, we immediately get that $|C| \leq \frac{3n - 6}{3} = n - 2$. This also holds obviously for planar graphs with a smaller connectivity number than 2. Nevertheless, we continue to use parameter $k$ when analyzing time complexity.

The main purpose of this section is to present a method of decomposing $G$ into subgraphs with respect to $C$ having certain desirable properties which support the construction of an embedding of $G$ satisfying given constraints. This decomposition is described in terms of $C$-components of $G$ for cycles $C \in C$. The fact that $G$ admits such a decomposition is mainly due to the cycle intersection order 1 of $C$; in particular, nonplanar graphs admit the same decomposition.

We denote the set of $C$-components in $G$ for all $C \in C$ with $H_C$ and often write $H_C$ for $C$-components $H$ of $G$. As a simple consequence of cycle
intersection order 1 of \( \mathcal{C} \), we have that \( C' \) must be entirely contained in some \( C \)-component of \( G \) for any distinct \( C, C' \in \mathcal{C} \); this \( C \)-component is denoted by \( H_{C,C'} \). The following lemma describes a frequently used relationship between \( C \)-components for different cycles of \( \mathcal{C} \).

**Lemma 1** Let \( G \) be a 2-connected graph, \( \mathcal{C} \) be a set of cycles in \( G \) with cycle intersection order 1 and \( C_1, C_2, C_3 \in \mathcal{C} \). Then, if \( C_2 \) and \( C_3 \) belong to different \( C_1 \)-components, \( C_1 \) and \( C_3 \) belong to the same \( C_2 \)-component.

**Proof:** We show that there is a path \( p \) in \( G \) from some vertex \( a \in V(C_1) \setminus V(C_2) \) to some vertex \( b \in V(C_3) \setminus V(C_2) \) such that \( p \) does not meet \( C_2 \). Then, since \( p \) is entirely contained in some \( C_2 \)-component, both \( C_1 \) and \( C_3 \) necessarily belong to that \( C_2 \)-component, too.

The \( C_1 \)-component \( H \) of \( G \) containing \( C_3 \) has at least 2 vertices of attachment, but by assumption \( |C_1 \cap C_2| \leq 1 \), at most one of them belongs to \( C_2 \). So let \( a \in V(C_1) \setminus V(C_2) \) be the other attachment vertex. Since \( C_2 \) is not contained in \( H \), \( C_2 \) can only meet \( H \) at its attachment points. Then let \( H' \subset H \) be the component of \( G - C_1 \) which contains vertices of \( C_3 \) and let \( b \) be such a vertex. Thus we have \( H' \cap C_2 = \emptyset \) and \( b \in V(C_3) \setminus V(C_2) \). Finally, if \( a \) already belongs to \( C_3 \), we define \( p \) to be the trivial path \( a \). Otherwise, if \( e \) is an edge joining \( a \) to some \( z \in H' \) and \( p' \) is a path in \( H' \) from \( z \) to \( b \), then \( p = e \cup p' \) is the required path from \( a \) to \( b \) without meeting \( C_2 \).

Any cycle \( C \in \mathcal{C} \) with more than one \( C \)-component divides \( G \) into just these \( C \)-components. It is more appropriate for our purpose, however, to take the union of these \( C \)-components with \( C \) as the subgraphs into which \( C \) divides \( G \). Having in mind the way how cutvertices divide a connected graph into blocks, one can ask whether there is a similar decomposition of \( G \) into maximal subgraphs that cannot be further divided by cycles of \( \mathcal{C} \). This motivates the following definition of *parts*.

**Definition 5** A subset \( \mathcal{C}' \) of \( \mathcal{C} \) with \( |\mathcal{C}'| \geq 2 \) is called separable if there is some \( C \in \mathcal{C} \) with at least two \( C \)-components in \( G \) each of which containing cycles from \( \mathcal{C}' \). Otherwise, \( \mathcal{C}' \) is called inseparable.

An inseparable \( \mathcal{C}' \) defines the subgraph \( P_{\mathcal{C}'} = \bigcap_{C \in \mathcal{C}'} C \cup \bigcup_{C \in \mathcal{C}'} H_C \) of \( G \) where \( H_C \) is the \( C \)-component containing all cycles from \( \mathcal{C}' \setminus \{C\} \).

We call the subgraphs \( P_{\mathcal{C}'} \) defined by some maximal inseparable \( \mathcal{C}' \) and the subgraphs \( C \cup H_C \) for a \( C \)-component \( H_C \) not containing cycles from \( \mathcal{C} \) parts of \( G \) w.r.t. \( \mathcal{C} \). The set of all parts is denoted by \( \mathcal{P} \).

The decomposition graph \( D \) is defined on \( \mathcal{C} \cup \mathcal{P} \) by the edges \( CP \) iff \( C \subset P \) for \( C \in \mathcal{C} \) and \( P \in \mathcal{P} \).

To illustrate these definitions, consider the graph \( G \) and its decomposition graph \( D \) shown in Fig. 14. For instance, \( \{C_5, C_8\} \) is separable since \( C_5 \) and \( C_8 \) belong to different \( C_1 \)-components. \( \{C_1, C_8\} \) is inseparable, but not maximal inseparable since \( \{C_1, C_8, C_7\} \) is also inseparable. This set, however, is maximal inseparable, thus defining a part. As we will see, the decomposition graph is always a tree.
The definition of maximal inseparable subsets and parts, however, is non-constructive. Thus we develop next an effective method for finding all maximal inseparable subsets of \( C \) which then can be transformed into a procedure for computing the parts of \( G \). For this purpose we define in Proposition 1 the relation \( \ll \) on \( C \) depending on some fixed root cycle \( C_r \). It is called weakly linear if \( C \ll C' \) and \( C \ll C'' \) imply \( C' \ll C'' \) or \( C' = C'' \) or \( C'' \ll C' \).

**Proposition 1** Let be \( C_r \in C \) and the relation \( \ll \) be defined on \( C \) by \( C \ll C_r \) and \( C' \ll C \) iff \( C' \notin H_{C,C_r} \) for all distinct \( C,C' \in C \setminus \{C_r\} \). Then, \( \ll \) is a weakly linear, strict partial order.

**Proof:** It is sufficient to consider only cycles distinct from \( C_r \). Obviously, \( \ll \) is asymmetric since \( C' \ll C \) implies by Lemma 1 that \( C_r \) and \( C \) are in the same \( C' \)-component, i.e. \( C \not\ll C' \).

To show transitivity, assume that \( C'' \ll C' \) and \( C' \ll C \) holds and suppose that \( C'' \not\ll C \). Since \( C'' \) and \( C_r \) are in the same \( C \)-component, but not \( C' \) and \( C_r \), we conclude that \( C \) and \( C'' \) are in the same \( C' \)-component. In connection with \( C'' \ll C' \) we then get \( C \ll C' \) in contradiction to asymmetry. Thus \( C'' \ll C' \) must hold.

To prove that \( \ll \) is weakly linear, assume that \( C \ll C' \) and \( C \ll C'' \) and further suppose that \( C' \neq C'' \) and \( C' \not\ll C'' \). The latter means that \( C' \) and \( C_r \) are in the same \( C'' \)-component, thus from \( C \ll C'' \) follows that \( C \) and \( C' \) are in different \( C'' \)-components. Then, by Lemma 1, \( C'' \) and \( C \) are in the same \( C' \)-component. In connection with \( C \ll C' \) this means that \( C'' \) and \( C_r \) are in different \( C' \)-components, thus \( C'' \ll C' \).

In other words, the transitive reduction of \( \ll \) is a rooted tree with root \( C_r \). For the example graph of Fig. 14 with \( C_1 \) chosen for \( C_r \), \( \ll \) is shown in Fig. 15.
Using the relation $\ll$, we are able to determine the maximal inseparable subsets $C'$ of $C$, no matter which cycle is the root cycle. We show in Theorem 7 that we get all maximal inseparable sets $C'$ by choosing some cycle $C$ and all direct successors $C'$ of $C$ in $\ll$ belonging to the same $C$-component of $G$. The cycle $C'$ is a successor of $C$ if $C' \ll C$ holds, and a direct successor if there is no $C''$ with $C' \ll C'' \ll C$. The proof of this theorem makes use of the following lemma on maximal inseparable sets.

**Lemma 2** Let $C' \subset C$ be maximal inseparable and $B \in C$ be a cycle not belonging to $C'$. Then, there is some $C' \in C'$ dividing $B$ from $C' \setminus \{C'\}$.

**Proof:** Since $C' \cup \{B\}$ is separable, there is a $B_1 \in C$, $B_1 \neq B$, dividing $B$ from all cycles of $C' \setminus \{B_1\}$. If $B_1 \in C'$, we are finished. Otherwise, since $C' \cup \{B_1\}$ is also separable, there is some $B_2 \in C$, $B_2 \neq B_1$, dividing $B_1$ from $C' \setminus \{B_2\}$. We show that $B_2$ also divides $B$ from $C' \setminus \{B_2\}$. By Lemma 1, $B_2$ and all cycles of $C'$ are in the same $B_1$-component, thus $B$ and $B_2$ are in different $B_1$-components. Again by Lemma 1, $B$ and $B_1$ are in the same $B_2$-component. Then we get that $B_2$ also divides $B$ from $C' \setminus \{B_2\}$.

If $B_2 \in C'$, we are finished. Otherwise, one can find again a $B_3 \in C$ dividing $B_2$, and thus $B$, from $C' \setminus \{B_3\}$, and so forth. This process results in some $B_i$ belonging to $C'$ that divides $B$ from $C' \setminus \{B_i\}$. □

**Theorem 7** Let $C'$ be a subset of $C$ with $|C'| \geq 2$. Then, $C'$ is maximal inseparable iff there is a $C \in C'$ such that $C' \setminus \{C\}$ is a set of all direct successors $C' \ll C$ belonging to the same $C$-component in $G$.

**Proof:** ($\Rightarrow$) Suppose $C'$ is maximal inseparable. By Proposition 1, there is a cycle $C \in C'$ that is maximal in $\ll |C'|$. Let $H$ be the $C$-component containing all the other cycles of $C'$. We first prove that all $C' \in C' \setminus \{C\}$ are successors of $C$. If $C' \in C'$, we have $C = C'$ and, by definition, $C' \ll C$ for all $C' \in C' \setminus \{C\}$. Otherwise we have $C' \not\subset C' \setminus \{C\}$. We show that $C'$ is not contained in $H$; then all $C' \in C' \setminus \{C\}$ are in a different $C$-component than $C_r$, thus it follows that $C' \ll C$. So suppose that $C_r \subset H$. Since $C'$ is maximal inseparable, from Lemma 2 follows that there is some $C^* \in C'$, $C^* \neq C_r$, dividing $C_r$ from $C' \setminus \{C^*\}$. $C^*$ must be identical with $C$: otherwise the maximality of $C$ implies $C \ll C^*$, i.e. $C^*$ does not divide $C_r$ from $C' \setminus \{C^*\}$. However, $C = C^*$ means...
that \( C_r \) is in a different \( C \)-component than all \( C' \in \mathcal{C}' \setminus \{ C \}, \) contrary to the assumption that \( C_r \subset H. \)

Next we show that all \( C' \in \mathcal{C}' \setminus \{ C \} \) are direct successors of \( C \) in \( \ll \). Suppose that there is some \( C^* \) with \( C' \ll C^* \ll C \). From \( C^* \ll C \) follows by Lemma 1 that \( C \) and \( C_r \) are in the same \( C^* \)-component. In connection with \( C' \ll C^* \) we get that \( C' \) and \( C \) are in different \( C^* \)-components. Then, however, \( C' \) would not be inseparable.

Finally, we have to show that any direct successor \( C' \) of \( C \) belonging to \( H \) is already contained in \( \mathcal{C}' \). Suppose that \( C' \not\in \mathcal{C}' \). By Lemma 2, there is some \( C^* \in \mathcal{C}' \), \( C^* \neq C' \), dividing \( C' \) from \( \mathcal{C}' \setminus \{ C^* \} \). From \( C^* \ll C \) follows that \( C_r \) and \( C \) are in the same \( C^* \)-component, and \( C^* \not\ll C^* \) means that \( C_r \) and \( C \) are in the same \( C^* \)-component. Then, \( C^* \) does not divide \( C' \) from \( C \) and, thus, from \( \mathcal{C}' \setminus \{ C^* \} \). This shows that \( C' \) must belong to \( \mathcal{C}' \).

\( (\Leftarrow) \) Suppose \( \mathcal{C}' \) satisfies the requirements where \( C \) is the maximal cycle. Let \( H \) be the \( C \)-component containing all other cycles of \( \mathcal{C}' \). We first show that \( \mathcal{C}' \) is inseparable. So let \( C^* \) be some cycle of \( \mathcal{C} \). If \( C^* \not\subset H \), \( C^* \) is in a different \( C \)-component than all \( C' \in \mathcal{C}' \setminus \{ C \} \). By Lemma 1, all \( C' \in \mathcal{C}' \) are in the same \( C^* \)-component. Suppose \( C^* \subset H \), thus in particular \( C^* \neq C \) and \( C^* \neq C_r \). If \( C^* \in \mathcal{C}' \), we have \( C^* \ll C \), i.e. \( C_r \) and \( C \) are in the same \( C^* \)-component. Since for all \( C' \in \mathcal{C}' \setminus \{ C \} \) we have \( C' \ll C \), and in particular \( C' \not\ll C^* \), \( C_r \) and \( C \) are in the same \( C^* \)-component. Thus, all \( C' \in \mathcal{C}' \) belong to the same \( C^* \)-component. Otherwise, if \( C^* \not\in \mathcal{C}' \), \( C^* \) must be a successor of some \( C'' \in \mathcal{C}' \setminus \{ C \} \) according to the assumption. From \( C^* \ll C' \ll C \) follows that \( C_r \), \( C' \) and \( C \) are in the same \( C^* \)-component. Since for all other \( C'' \in \mathcal{C}' \setminus \{ C, C' \} \) we have \( C'' \not\ll C^* \), it follows that \( C_r \) and \( C'' \) are in the same \( C^* \)-component. Thus, all \( C' \in \mathcal{C}' \) again belong to the same \( C^* \)-component.

Next we prove that \( \mathcal{C}' \) is maximal inseparable. Suppose that for some \( C^* \not\in \mathcal{C}' \), \( \mathcal{C}' \cup \{ C^* \} \) is also inseparable. Then \( C^* \) must be contained in \( H \). By assumption, \( C^* \) must be a successor of some \( C' \in \mathcal{C}' \setminus \{ C \} \), i.e. \( C^* \) and \( C_r \) are in different \( C \)-components. From \( C' \ll C \) follows that \( C \) and \( C_r \) are in the same \( C^* \)-component. Thus, \( C^* \) and \( C \) are in different \( C^* \)-components such that \( \mathcal{C}' \cup \{ C^* \} \) is separable.

From the results shown above we get some immediate consequences characterizing parts and decomposition graphs in more detail. We summarize them in Corollary 3 and 4.

**Corollary 3** Let \( \mathcal{P} \) be the set of parts of \( G \) w.r.t. \( \mathcal{C} \). Then the following propositions hold:

(i) Any part \( P_{C'} \in \mathcal{P} \) contains exactly the cycles \( C' \) from \( \mathcal{C} \).

(ii) Any cycle \( C \in \mathcal{C} \) in some part \( P \in \mathcal{P} \) has exactly one \( C \)-component in \( P \).

(iii) For any part \( P \in \mathcal{P} \) and cycle \( C \in \mathcal{C} \) we have \( P \subset C \cup H_C \) for some \( C \)-component \( H_C \) of \( G \).

(iv) Two distinct parts \( P, P' \in \mathcal{P} \) have at most one cycle of \( \mathcal{C} \) in common.
Corollary 4 Let \( \mathcal{P} \) be the set of parts and \( D \) be the decomposition graph of \( G \) w.r.t. \( C \). Then the following propositions hold:

(i) \( D \) is a tree with \( |D| < n \).

(ii) If \( H_C \) is a \( C \)-component of \( G \), then \( P \) is the part of \( G \) such that

\[
C \subset P \subset C \cup H_C,
\]

then \( C \cup H_C \) is the union of all parts belonging to the component of \( D - C \) which contains \( P \).

(iii) \( G \) has less than \( n \) \( C \)-components, i.e. \( |H_C| < n \).

The usefulness of decomposing \( G \) into its parts for the embedding algorithm to be developed comes in particular from Proposition (ii) of Corollary 3: it guarantees that any cycle of \( C \) in some part \( P \) is a facial cycle of any embedding of \( P \). As we will see in Sect. 5.2, this allows controlling the satisfaction of constraints during the embedding process. By Proposition (ii) of Corollary 4, we have a one-to-one correspondence \( \varepsilon \) between \( C \)-components of \( G \) and edges of \( D \): each edge \( CP \in E(D) \) represents the \( C \)-component \( H_C \) with \( C \subset P \subset C \cup H_C \), thus we define \( \varepsilon(H_C) = CP \). This correspondence ensures the decomposition graph \( D \) to be a complete representation of the structure of \( G \) w.r.t. \( C \).

The method for finding the maximal inseparable subsets of \( C \) provided by Theorem 7 leads directly to an efficient procedure for computing the parts of \( G \). The order in which the cycles are processed plays a crucial role in this procedure. Suppose \( \ll \) is defined by some fixed cycle \( C_r \) and the cycles of \( C \) are in the reverse order \( C_1, \ldots, C_k \) of some topological sorting, i.e. \( C_j \ll C_i \) implies \( j < i \). Thus, we always have \( C_k = C_r \). Define \( G_0 = G \) and \( P_1, G_i, E_i \) for \( 1 \leq i \leq k \)

\[
\begin{align*}
P_i &= \{ C_i \cup H \mid H \text{ is a } C_i\text{-component of } G_{i-1} \text{ with } C_r \not\subset H \} , \\
G_i &= C_i \cup H_i , \text{ for the } C_i\text{-component } H_i \text{ of } G_{i-1} \text{ with } C_r \subset H_i , \\
E_i &= \{ C'P \mid C' \in C \text{ and } C' \subset P \in P_i \} .
\end{align*}
\]

Defining \( \mathcal{P}_{C_r} = \bigcup P_i \) and the graph \( D_{C_r} \) on \( C \cup \mathcal{P}_{C_r} \) by the edge set \( \bigcup E_i \), it can easily be seen in Proposition 2 that \( \mathcal{P}_{C_r} \) is in fact the set of all parts of \( G \) and \( D_{C_r} \) is its decomposition graph.

Proposition 2 For any \( C_r \in \mathcal{C} \mathcal{P}_{C_r} \) is the set of parts and \( D_{C_r} \) is the decomposition graph \( D \) of \( G \) w.r.t. \( C \). Moreover, \( \mathcal{P} \) and \( D \) can be computed by an \( O(nk) \) procedure.

Proof: By the definition of the \( E_i, D_{C_r} = D \) follows from \( \mathcal{P}_{C_r} = \mathcal{P} \). Due to the particular order of the cycles \( C_i \), the successors \( C_j \) of \( C_i \) contained in \( G_{i-1} \) are exactly the direct successors of \( C_i \). Moreover, each \( C_j \) has only one \( C_j \)-component in \( G_{i-1} \), namely that one which contains \( C_i \) and \( C_r \). By Theorem 7, \( \mathcal{P}_i \) contains exactly the parts built by \( C_i \) and its direct successors \( C_j \) belonging
to the same $C_i$-component and also the parts built by $C_i$ and a $C_i$-component not containing any other cycle of $\mathcal{C}$.

Finally, it can easily be seen that a procedure can be implemented for generating $P$ and $D$ which takes $O(nk)$ time. The relation $\ll$ can be determined for some fixed $C_r$ by computing all $C$-components in $H_C$ which needs $O(nk)$ time. The topological sorting can be done in $O(k^2) = O(nk)$ time. And in each step $i$ the determination of all $C_i$-components of $G_{i-1}$ takes $O(n)$ time. Thus the overall complexity is $O(nk)$. \hfill $\Box$

Figure 16 illustrates the stepwise construction of the parts of graph $G$ given in Fig. 14. The sequence of cycles is $C_3, C_4, C_2, C_5, C_6, C_7, C_8, C_1$ which is the reverse order of some topological sorting of the relation $\ll$ shown in Fig. 15.

5.1.1 Representing Embeddings by Labelled Decomposition Graphs

Decomposition graphs are particularly interesting for the planarity problem with topological constraints. We show in this section that labelled decomposition graphs can represent, in a sense, embeddings of 2-connected planar graphs up to topological constraints, i.e. all embeddings corresponding to the same labelled decomposition graph satisfy the same topological constraints involving cycles from $\mathcal{C}$.

Consider an embedding $\tilde{G}$ of $G$. Due to the correspondence between edges of $D$ and $C$-components of $G$, we can label each edge $CP$ with the binary information on which side of $C$ the $C$-component $H_C$ corresponding to $CP$ is
embedded in $\tilde{G}$. If $\tilde{P} \subset \text{Int} \tilde{C}$ holds in $\tilde{G}$, we label $CP$ with 1 and otherwise, if $\tilde{P} \subset \text{Ext} \tilde{C}$, we label $CP$ with 0. Obviously, edges representing overlapping $C$-components have complementary labels. Since $\tilde{G}$ defines a weakly linear, strict partial order $< \text{on} \ C$ by $C' < C$ iff $\text{Int} \tilde{C}' \subset \tilde{C}$, there is at least one maximal $C_r \in C \text{w.r.t.} <$ contained in the exterior of any other cycle of $C$. As a consequence, for any path $C_r, \ldots, P, C$ in $D$ the edge $PC$ is labelled with 0. Thus $G$ induces a labelling of $D$ according to the following definition.

**Definition 6** Let $D$ be the decomposition graph of $G$ w.r.t. $C$. A labelling $\lambda$ of $D$ is a function $\lambda : E(D) \rightarrow \{0,1\}$ satisfying the following conditions:

1. $\lambda(\varepsilon(H_C)) + \lambda(\varepsilon(H'_C)) = 1$ for overlapping $C$-components $H_C$ and $H'_C$.
2. There is a $C_r \in C$ such that for all paths $C_r, \ldots, P, C$ in $D$: $\lambda(PC) = 0$.

A labelling of $D$ together with $D$ is called a labelled decomposition graph.

Suppose $\tilde{G}$ and $\tilde{G}'$ are embeddings of $G$ inducing the same labelling of $D$. Then any $C$-component $H_C$ is inside $C$ in $\tilde{G}$ iff it is inside $C$ in $\tilde{G}'$, i.e. $G$ and $G'$ satisfy the same topological constraints involving cycles from $C$. However, $\tilde{G}$ and $\tilde{G}'$ need not necessarily be topologically equivalent, they can differ in the particular embeddings of the $C$-components. Conversely, if two embeddings of $G$ induce different labellings of $D$, they must be distinguished by at least one topological constraint. For this reason labelled decomposition graphs represent embeddings up to topological constraints. For the example graph $G$ of Fig. 14 an embedding of $G$ together with its labelled decomposition graph is shown in Fig. 17.

![Figure 17](image-url)

Figure 17: (a) An embedding of the graph $G$ given in Fig. 14. (b) The decomposition graph $D$ of $G$ with a labelling induced by this embedding.

Given a labelling $\lambda$ of $D$, one can easily construct an embedding of $G$ which induces exactly $\lambda$: one has only to embed $C_r$ and then attach in a depth-first
manner all parts $P$ to the already embedded cycle $C$ for edges $CP \in E(D)$ according to the label of $CP$. Algorithm embedding shown in Fig.18 describes this embedding procedure more precisely. Depending on the labelling $\lambda$, it generates a set $F$ of pairs $\langle F, S_F \rangle$ where $F$ is a cycle in $G$ and $S_F \subseteq C$; the cycles $F$ are called cycles of $F$ and $S_F$ are called their labels. If we choose some $\langle F_0, \emptyset \rangle$ from $F$, which is guaranteed to exist, $F_0$ is the outer facial cycle and the cycles of $F$ are the facial cycles of some embedding of $G$ that induces $\lambda$. In this case the inner facial cycles of any $C \in C$ are exactly those cycles $F$ of $F$ with $C \in S_F$.

Algorithm embedding

Input: labelling $\lambda$, $C \in C$, $F \subset \mathcal{C}(G) \times 2^C$
Output: $F$

For each edge $CP \in E(D)$ do:
1. Let $H$ be the (unique) $C$-component in $P$. Find some pair $\langle F, S_F \rangle \in F$ such that $F$ contains all vertices of attachment of $H$ and $C \in S_F$ if $\lambda(CP) = 1$.
2. Determine the set $F'$ of facial cycles of some embedding of $H \cup F$.
3. Remove $\langle F, S_F \rangle$ from $F$ and add $\langle F', S_F \rangle$ to $F$ for all $F' \in F' \setminus \{F\}$.
4. For any edge $PC' \in E(D)$ set $S_{C'} := S_{C'} \cup \{C'\}$ for cycle $C'$ of $F$ and compute $\text{embedding}(\lambda, C', F)$.

Return $F$.

Figure 18: Algorithm for generating an embedding corresponding to a labelled decomposition graph

To illustrate the construction of an embedding, Fig.19 shows the sequence of partial embeddings of the example graph according to the labelling given in Fig.17 (b). This sequence corresponds to the sequence of the sets $F$ of facial cycles generated by some depth-first search of $D$. For each visited edge $CP$ $H$ is the grey-colored subgraph and $F$ is the face cycle it is attached to. The correctness of this algorithm is proved in Proposition 3.

**Proposition 3** Let $\lambda$ be a labelling of the decomposition graph of $G$ w.r.t. $\mathcal{C}$. Then algorithm embedding generates a set $F$ of pairs $\langle F, S_F \rangle$ with cycle $F \subseteq G$ and $S_F \subseteq C$. $F$ satisfies the following conditions (where $F(C)$ denotes $\{F \mid \langle F, S_F \rangle \in F \text{ with } C \in S_F \}$):

(i) $\{F \mid \langle F, S_F \rangle \in F\}$ is the set of facial cycles of some embedding of $G$.

(ii) There is some $\langle F_0, \emptyset \rangle \in F$.

(iii) $C = \bigoplus_{F \in F(C)} F$ for all $C \in \mathcal{C}$.

(iv) $P \subseteq \bigcup_{F \in F(C)} F$ if $\lambda(CP) = 1$ for $CP \in E(D)$.
Moreover, the algorithm takes $O(n^2)$ time.

Proof: Define $\mathcal{F}_0 = \{\langle C_r, \emptyset \rangle, \langle C_r, \{C_r\} \rangle \}$ and for $i = 1, \ldots, |P| \mathcal{F}_i$ to be the sets $\mathcal{F}$ generated by the depth-first search of the algorithm. Note that the number of visited edges $CP \in E(D)$ is identical with the number of parts of $G$. Let $\mathcal{F}_i(C)$ denote $\{F \mid \langle F, S_F \rangle \in \mathcal{F}_i \text{ with } C \in S_F \}$. We show by induction that the following propositions hold for all $i \geq 0$; then, since $G$ is the union of all of its parts, $\mathcal{F}_{|P|}$ satisfies the claim.

(i) $\{F \mid \langle F, S_F \rangle \in \mathcal{F}_i \}$ is the set of facial cycles of some embedding of $\bigcup_{F' \in \mathcal{F}_i} F'$.

(ii) There is some $\langle F_0, \emptyset \rangle \in \mathcal{F}_i$.

(iii) $C = \bigoplus_{F' \in \mathcal{F}_i(C)} F'$ if $\mathcal{F}_i(C) \neq \emptyset$.

(iv) If for $CP \in E(D)$ $P \subset \bigcup_{F' \in \mathcal{F}_i} F'$, then $P \subset \bigcup_{F' \in \mathcal{F}_i(C)} F'$ iff $\lambda(CP) = 1$.

Clearly, $\mathcal{F}_0$ satisfies all these conditions. We assume them to hold for all $j \leq i$ for some $i$. Let $CP$ be the currently visited edge of $D$ and $H$ be the $C$-component of $P$. Due to condition (1) of Definition 6 and (i), there is some pair $\langle F, S_F \rangle \in \mathcal{F}_i$ such that $F$ contains the vertices of attachment of $H$ and $C \in S_F$ iff $\lambda(CP) = 1$. Let $\mathcal{F}'$ be the generated set of facial cycles of some embedding of $H \cup F$. By Corollary 3 (ii), $F$ and all $C' \in C$ with $PC' \in E(D)$ are facial cycles of this embedding and, thus, are contained in $\mathcal{F}'$. Moreover, we have $F = \bigoplus_{F' \in \mathcal{F}_i \setminus \{F\}} F'$. 

Figure 19: Illustration of algorithm embedding for the labelled decomposition graph $D$ of Fig. 17 (b). For each edge $CP$ $H$ is the grey-colored subgraph and $F$ the face cycle it is attached to.
By the definition of $\mathcal{F}_{i+1} := \mathcal{F}_i \setminus \{(F, S_F)\} \cup \{(F', S_{F'}) \mid F' \in \mathcal{F}' \setminus \{F\}\}$ and $S_{C'} := S_C \cup \{C'\}$, the conditions (i)–(iv) can be easily verified. Condition (i) holds since $\mathcal{F}' \setminus \{F\}$ is a refinement of $F$ and (ii) holds because of cycle intersection order 1 of $C$. Condition (iii) is shown for $C'$ with $PC' \notin E(D)$ by

$$\bigoplus_{F' \in \mathcal{F}_{i+1}(C')} F' = \bigoplus_{F' \in \mathcal{F}_i(C') \setminus \{F\}} F' \oplus \bigoplus_{F' \in \mathcal{F}' \setminus \{F\}} F' = \bigoplus_{F' \in \mathcal{F}_i(C')} F' = C'$$

and for $C'$ with $PC' \in E(D)$ by $\mathcal{F}_{i+1}(C') = \{C'\}$. The last condition (iv) follows immediately from the choice of $F$ depending on $\lambda(CP)$ and condition (2) of Definition 6.

Finally, we note that this algorithm can be implemented as an $O(n^2)$ procedure since $G$ has less than $n$ parts and steps 1 to 4 can be done in $O(n)$ time. 

\square

### 5.2 A Polynomial Time $T_1$-Embedding Algorithm

Provided with the analysis of the previous sections, we are now able to present a polynomial time algorithm for generating $T_1$-embeddings of planar graphs. This algorithm is a combination of the reduction algorithms given in Sect. 4 and the procedure for generating $T\Lambda\chi$-embeddings of 2-connected graphs which we develop next. So let $G$ denote a 2-connected planar graph and $T$, $\mathcal{L}$ and $\mathcal{X}$ denote a set of topological constraints, overlap constraints and extended overlap constraints for $G$, respectively, such that the set $\mathcal{C}$ of all cycles involved in these constraints is of cycle intersection order 1. Moreover, we denote $n = |G|$, $t = |T|$, $l = |\mathcal{L}|$, $x = |\mathcal{X}|$ and $k = |\mathcal{C}|$.

The main idea for generating a $T\Lambda\chi$-embedding of $G$ is finding an appropriate labelling of the decomposition graph $D$ of $G$ w.r.t. $\mathcal{C}$ depending on $T$, $\mathcal{L}$ and $\mathcal{X}$ that can be transformed by algorithm embedding into a $T\Lambda\chi$-embedding. For this purpose, we determine edges of $D$ whose labels can be deduced from the constraints and, thus, necessarily belong to this labelling. To find labels according to condition (1) of Definition 6, we make use of overlap graphs $G_C$ of cycles $C \in \mathcal{C}$. Consider a component $Z$ of $G_C$ with at least two $C$-components. Since $G_C$ is bipartite, $Z$ has a unique partition $Z = Z_1 \cup Z_2$ such that both $Z_1$ and $Z_2$ contain no overlapping $C$-components. Then, a label for $CP \in E(D)$ with $CP = \varepsilon(H_C)$ for some $C$-component $H_C \in Z$ clearly determines the labels of edges representing all the other $C$-components in $Z$. We denote with $[CP]$ the set of edges representing all the $C$-components belonging to the same part of the partition as $CP$ and denote with $[CP]^-$ the set of edges representing all the $C$-components belonging to the other part. Thus, two edges of $[CP]$ and $[CP]^-$, respectively, must have complementary labels. We call $[CP]$ the equivalence class of $CP$ and $[CP]^-$ its complement.

With the following definitions we determine equivalence classes of edges of $D$ whose labels can be easily deduced from the constraints. $E_1(T)$ and $E_0(T)$ are the sets of equivalence classes whose edges must have label 1 and 0, respectively, due to the topological constraints in $T$. The sets $E_1(\mathcal{L})$, $E_0(\mathcal{L})$ and
$E_1(\mathcal{X}), E_0(\mathcal{X})$ are to be interpreted analogously. Note, however, that these sets are not meant to cover all labels that can be deduced.

$$E'_1(T) = \{[\varepsilon(H_C)] \mid H_C \cap \text{In}_C \neq \emptyset \text{ for } H_C \in \mathcal{H}_C, \langle C, \text{In}_C, \text{Out}_C \rangle \in T\}$$

$$E'_0(T) = \{[\varepsilon(H_C)] \mid H_C \cap \text{Out}_C \neq \emptyset \text{ for } H_C \in \mathcal{H}_C, \langle C, \text{In}_C, \text{Out}_C \rangle \in T\}$$

$$E_1(T) = E'_1(T) \cup \{[CP]^- \mid [CP] \in E'_0(T)\}$$

$$E_0(T) = E'_0(T) \cup \{[CP]^- \mid [CP] \in E'_1(T)\}$$

$$E_0(\mathcal{L}) = \{[\varepsilon(H_{C,C'})] \mid C \in \text{C-Out}_i, C' \in \text{C-In}_i \text{ for } \langle \text{C-In}_i, \text{C-Out}_i \rangle \in \mathcal{L}\}$$

$$E_1(\mathcal{L}) = \{[CP]^- \mid [CP] \in E_0(\mathcal{L})\}$$

$$E''_0(\mathcal{X}) = \{[\varepsilon(H_{C,C'})] \mid C \in \text{C-Out}_i, C' \in \text{C-In}_i, \langle \text{C-In}_i, \text{C-Out}_i, v \rangle \in \mathcal{X}\}$$

$$E''_1(\mathcal{X}) = \{[\varepsilon(H_C)] \mid v \notin C \in \text{C-In}_i, v \in H_C \in \mathcal{H}_C, \langle \text{C-In}_i, \text{C-Out}_i, v \rangle \in \mathcal{X}\}$$

$$E'_1(\mathcal{X}) = \{[\varepsilon(H_C)] \mid v \in C \in \text{C-In}_i, v \in H_C \in \mathcal{H}_C, \langle \text{C-In}_i, \text{C-Out}_i, v \rangle \in \mathcal{X}\}$$

$$E_1(\mathcal{X}) = E'_1(\mathcal{X}) \cup \{[CP]^- \mid [CP] \in E'_0(\mathcal{X}) \cup E''_0(\mathcal{X})\}$$

$$E_0(\mathcal{X}) = E''_0(\mathcal{X}) \cup E'_0(\mathcal{X}) \cup \{[CP]^- \mid [CP] \in E'_1(\mathcal{X})\}$$

As a result, we define $E_1 = E_1(T) \cup E_1(\mathcal{L}) \cup E_1(\mathcal{X})$ and $E_0 = E_0(T) \cup E_0(\mathcal{L}) \cup E_0(\mathcal{X})$. Next we consider overlap constraints and extended overlap constraints in more detail. By their semantics and cycle intersection order 1 of $\mathcal{C}$, the cycles of $\text{C-In}_i$ belonging to some $L_i \in \mathcal{L}$ or $X_i \in \mathcal{X}$ are embedded in any $\mathcal{T \mathcal{L} \mathcal{X}}$-embedding of $G$ in a linear order w.r.t. the induced relation $< \circ$. Thus, they must necessarily belong to a path of $D$ if $G$ is $\mathcal{T \mathcal{L} \mathcal{X}}$-planar. If this holds for $L_i = \langle \text{C-In}_i, \text{C-Out}_i \rangle$, we denote $w(L_i)$ the smallest path containing all cycles of $\text{C-In}_i$ and say that $L_i$ induces $w(L_i)$; the constraints of $\mathcal{X}$ are treated analogously. Suppose such a path is of the form $C_1, P_1, \ldots, P_j, C_j, P'_j, \ldots, P_s, C_s$ with $C_1, C_j$ and $C_s$ belonging to a set $C_{\text{In}_i}$. Then in a $\mathcal{T \mathcal{L} \mathcal{X}}$-embedding either $C_1 < \ldots < C_j < \ldots < C_s$ or $C_s < \ldots < C_j < \ldots < C_1$ holds. We define the set $E_\ast$ of equivalence classes whose edges potentially get label 1, due to these two cases, during the search for an appropriate labelling:

$$E_\ast = \{[CP] \mid CP \in E(w(L_i)), C \in \text{C-In}_i \text{ if } L_i \in \mathcal{L} \text{ induces } w(L_i)\} \cup \{[CP] \mid CP \in E(w(X_i)), C \in \text{C-In}_i \text{ if } X_i \in \mathcal{X} \text{ induces } w(X_i)\}.$$}

To construct an appropriate labelling, we have to find in particular a $C_r \in \mathcal{C}$ satisfying condition (2) of Definition 6. For each edge $CP \in E(D)$ let $R_{CP}$ be the set $\{C' \in \mathcal{C} \mid C' \notin \varepsilon^{-1}(CP)\}$, i.e. the set of cycles not contained in the $C$-component represented by $CP$. We can restrict the set of candidates for $C_r$ with the help of $R_{CP}$: suppose $CP$ has label 1, then no cycle in $\mathcal{C} \setminus R_{CP}$ can satisfy condition (2). Moreover, consider a path $w(L_i)$ whose first and last edges are $CP$ and $CP'$, respectively. Then we can restrict the set of candidates to $R_{CP} = R_{CP} \cup R_{CP'}$; $R_{CP}$ is defined analogously. From what is considered so far, we have the following set of candidates:

$$R = \bigcap_{[CP] \in E_1} R_{CP} \cap \bigcap_{L_i \in \mathcal{L}} R_{L_i} \cap \bigcap_{X_i \in \mathcal{X}} R_{X_i}.$$}

In Definition 7 we establish the criterion of being an appropriate labelling that respects the constraints $\mathcal{T}$, $\mathcal{L}$ and $\mathcal{X}$, thus we call it $\mathcal{T \mathcal{L} \mathcal{X}}$-labelling.
Definition 7 A $T LX$-labelling $\lambda$ of $D$ is a labelling satisfying the following additional conditions:

1. $\lambda(\text{CP}) = 1$ if $[\text{CP}] \in E_1$.
2. $\lambda(\text{CP}) = 0$ if $[\text{CP}] \in E_0$.
3. $C_r \in R$; each $L_i \in L$ and $X_i \in X$ induces in particular a path in $D$.
4. For all paths $C_r, \ldots, C, P$ with $[\text{CP}] \in E^*$: $\lambda(\text{CP}) = 1$.

Clearly, any $T LX$-embedding of $G$ induces a $T LX$-labelling on $D$. It can also easily be verified by Proposition 3 that the converse holds as well: given a $T LX$-labelling of $D$, algorithm embedding generates some $\langle F, S_F \rangle$ such that each $F_0$ with $\langle F_0, \emptyset \rangle$ is the outer facial cycle and the cycles of $F$ are the facial cycles of some $T LX$-embedding of $G$.

The algorithm find labelling in Fig. 20 generates a $T LX$-labelling of $D$ iff $G$ is $T LX$-planar. Its main part is a depth-first search of $D$ beginning at a candidate $C_r \in R$ that labels the visited edges. We consider $D$ a directed tree with root $C_r$ such that each edge is uniquely denoted by $CP$ or $PC$ depending on whether $C_r, \ldots, C, P$ or $C_r, \ldots, P, C$ is a path in $D$. When attaching labels to edges, labelling an edge with 0 or 1 fails if this edge already has the complementary label 1 or 0, respectively. Proposition 4 establishes the correctness of the algorithm.

Algorithm find labelling
Input: decomposition graph $D$ of $G$, constraints $T, L, X$
Output: $T LX$-labelling $\lambda$ with the particular $C_r \in C$

1. Determine $E_1$ and $E_0$. If $E_1 \cap E_0 \neq \emptyset$, stop.
   Check if each $L_i \in L$ and $X_i \in X$ induces a path in $D$; if not so, stop.
   Determine $E_*$ and $R$. If $R = \emptyset$, stop.
2. Label any edge $CP$ of $D$ with 1 if $[CP] \in E_1$, and with 0 if $[CP] \in E_0$.
   Then label any edge $CP$ not labelled so far with $*$ if $[CP] \in E_*$.
3. Find a $C_r \in R$ such that the following operations executed during a depth-first search of $D$ beginning at $C_r$ are successful:
   3.1 If edge $PC$ is visited, label all edges in $[PC]$ with 0 and all edges in $[PC]^-$ with 1.
   3.2 If edge $CP$ with label $*$ is visited, label all edges in $[CP]$ with 1 and all edges in $[CP]^-$ with 0.
   3.3 If edge $CP$ without any label is visited, label all edges in $[CP]$ with 0 and all edges in $[CP]^-$ with 1, or vice versa.
4. If this succeeds, return $C_r$ and labelling $\lambda$ defined by the labels of $D$.

Figure 20: Algorithm for generating a $T LX$-labelling of the decomposition graph
Proposition 4 Given constraints $T$, $L$ and $X$ for $G$, algorithm $\text{find\_labelling}$ generates a $T \mathcal{L} \mathcal{X}$-labelling iff $G$ is $T \mathcal{L} \mathcal{X}$-planar. Moreover, the algorithm takes $O \left( n^2 k + kl + kx \right)$ time.

Proof: $(\Rightarrow)$ It can easily be seen that the set of labels generated by the algorithm defines in fact a $T \mathcal{L} \mathcal{X}$-labelling $\lambda$ of $D$. Since for any edge $CP \in E(D)$ the edges in $[CP]$ and in $[CP]^{-}$ have complementary labels and, moreover, each edge has a unique label 0 or 1, condition (1) of Definition 6 is satisfied. Condition (2) is guaranteed by step 3.1, thus $\lambda$ is a labelling. Conditions (1) and (2) of Definition 7 are ensured by step 2 and (3) is checked in step 1 and 3. The last condition (4) holds because of step 3.2. Thus $\lambda$ is a $T \mathcal{L} \mathcal{X}$-labelling and $G$ is $T \mathcal{L} \mathcal{X}$-planar.

$(\Leftarrow)$ Suppose $G$ has a $T \mathcal{L} \mathcal{X}$-embedding. Then there is a $T \mathcal{L} \mathcal{X}$-labelling $\lambda'$ induced by this embedding. In particular, we have that $E_1 \cap E_0 = \emptyset$, each $L_i \in L$ and $X_i \in X$ induces a path in $D$ and $R \neq \emptyset$. Since for any edge $CP$ of $D$ labelled in step 2 with 0 or 1 it necessarily holds that $\lambda'(CP) = 0$ or $\lambda'(CP) = 1$, respectively, and the cycle $C_r$ is searched exhaustively in $R$, it is guaranteed that the algorithm finds a complete set of labels for $D$ which defines a $T \mathcal{L} \mathcal{X}$-labelling as shown above.

Finally, we estimate the time complexity of this algorithm. To determine the sets in step 1, it is necessary to find the overlap graphs of cycles of $C$ which can be done in $O(kn^2)$ time. Then, determining the sets $E_1(T)$, $E_0(T)$ and $E_1(L)$, $E_0(L)$ and $E_1(X)$, $E_0(X)$ needs $O(nt)$, $O(kt)$ and $O(kx)$ time, respectively. Finding the paths induced by the constraints in $L$ and $X$ and determining $E_5$ can be done in $O(nl + nx)$ time. Moreover, the set $R$ can be computed in $O(nk + lk + xk)$ time. Next, labelling edges in step 2 and during the depth-first search of $D$ needs $O(n)$ time, thus step 3 takes $O(kn)$ time. The resulting time complexity is therefore $O(n^2k + kl + kx)$. □

Consider again the example graph of Fig. 14 and suppose we have a topological constraint meaning that cycle $C_6$ should be embedded inside cycle $C_1$ and an overlap constraint meaning that $C_1$ and $C_3$ should include a common face. The first constraint determines the set $E_1(T) = \{ [C_1P_3] \}$ and, thus, $E_0(T) = \{ [C_1P_3] = [C_1P_4] \}$. The other sets for $L$ and $X$ are empty. Because of the second constraint we get $E_2 = \{ [C_1P_3], [C_2P_4], [C_3P_5], [C_3P_6] \}$ indicating that $C_1$, $C_2$ and $C_3$ are to be embedded in some linear inclusion order. The set of candidates is $R = \{ C_1, C_3, C_5, C_7, C_8 \}$. Algorithm $\text{find\_labelling}$ encodes these sets by the partial labelling shown in Fig. 21 (a). In figure (b) we see some complete labelling that can result from this partial labelling when $C_1$ is chosen for $C_1$; it corresponds to the embedding shown in Fig. 17.

The complete $T \mathcal{L} \mathcal{X}$-embedding algorithm is shown in Fig. 22. Its correctness and complexity can be easily obtained from what is developed so far.
Figure 21: Illustration of algorithm find\_labelling: (a) A partial labelling encoding a topological constraint and an overlap constraint. (b) A complete labelling produced by the algorithm.

**Algorithm embedding\_with\_constraints**

*Input*: $G$, constraints $T$, $L$, $X$

*Output*: $T\LX$-embedding of $G$

1. Determine the decomposition graph $D$ of $G$.
2. Compute $\text{find\_labelling}(D, T, L, X)$ resulting in a labelling $\lambda$ and cycle $C_r$ if $G$ is $T\LX$-planar; otherwise stop.
3. Compute $\text{embedding}(\lambda, C_r\{(C_r, \emptyset), (C_r, \{C_r\})\})$ resulting in $(\mathcal{F}, S_\mathcal{F})$.
4. Embed $G$ such that the cycles of $\mathcal{F}$ are the facial cycles and $F_0$ is the outer facial cycle for some $(F_0, \emptyset) \in \mathcal{F}$.

Figure 22: Algorithm for generating a $T\LX$-embedding

**Proposition 5** Given $T$, $L$, $X$ for $G$, algorithm embedding\_with\_constraints generates a $T\LX$-embedding iff $G$ is $T\LX$-planar. Moreover, it takes $O(n^2k + kl + kx)$ time.

The combination of algorithm embedding\_with\_constraints with algorithm reduce\_to\_blocks and algorithm reduce\_to\_components leads to the complete $T_1$-embedding procedure for planar graphs. Using Corollary 1 and 2 of Theorem 5, we get the complexity of this procedure depending on whether $G$ is disconnected, connected or 2-connected.

**Theorem 8** Suppose $G$ is a planar graph with $n = |G|$ and $T$ is a set of topological constraints for $G$ of cycle intersection order 1 with $t = |T|$. Then the following propositions hold:
(i) If $G$ is disconnected, a $T$-embedding can be found in $O(n^6)$ time.

(ii) If $G$ is connected, a $T$-embedding can be found in $O(n^5)$ time.

(iii) If $G$ is 2-connected, a $T$-embedding can be found in $O(n^2t)$ time.

6 Conclusions

This paper contributes to the relatively new research direction on planar graph embedding with user-defined constraints. We introduced a special sort of constraints, called topological constraints, and studied the problem of finding an embedding satisfying a given set of topological constraints. As this problem turned out to be NP-complete, we developed a polynomial time procedure for reducing the problem for arbitrary planar graphs to a problem for biconnected graphs which allows to focus on biconnected graphs when searching for heuristics or tractable subproblems. This reduction, however, results in another two types of constraints one has to cope with in developing embedding algorithms. We then used this reduction for studying a particular subproblem defined by a parameter called cycle intersection order. With respect to this parameter, we proved the exact boundary between P and NP by showing that this subproblem remains NP-complete if the cycle intersection order exceeds 1 and by presenting a polynomial time embedding algorithm for cycle intersection order 0 or 1.
