We present an experimental realization of an autonomous Maxwell’s demon, which extracts microscopic information from a system and reduces its entropy by applying feedback. It is based on two capacitively coupled single-electron devices, both integrated on the same electronic circuit. This setup allows a detailed analysis of the thermodynamics of both the demon and the system as well as their mutual information exchange. The operation of the demon is directly observed as a temperature drop in the system. We also observe a simultaneous temperature rise in the demon arising from the thermodynamic cost of generating the mutual information.

Thermodynamic processes are governed by fundamental laws, of which the first, conservation of energy, is paramount in all fields of physics and cannot be violated at any level of description known to date. The second law in turn states that entropy, the measure of disorder, of a closed system cannot decrease. This has most important consequences, such that heat flows from hot to cold, irreversible processes must dissipate work, and devices of perpetual motion are impossible. To challenge this law, Maxwell presented a thought experiment in 1867 of a “finite being” capable of accurately measuring the velocity of molecules [1]. It would act between two separated reservoirs, permitting only fast molecules to enter one reservoir, while allowing only the slow ones to the other. Under such a process heat is transferred from cold to hot, apparently in violation of the second law. This idea, coined as “Maxwell’s demon” by Lord Kelvin, has over a century spurred further research on the relation between information and energy establishing quantitative relations [2–12]. Ongoing progress in nanotechnology has also provided concrete means to test such relations experimentally [13–23], thus reigniting acute interest in actually constructing a demon.

Recently, several theoretical proposals on configurations including both the system as well as the demon have been presented [7,24–26]. Such a configuration is known as an autonomous Maxwell’s demon, for the fact that the measurement and feedback operation takes place internally. Here, we experimentally realize an all-in-one Maxwell’s demon, whose operation principle is illustrated in Fig. 1(a). The system is a single-electron transistor (SET) [27], formed by a small normal metallic island connected to two normal metallic leads by tunnel junctions. The two junctions permit electron transport by tunneling, and are assumed to be identical (both with the same resistance $R_s$). The demon measures the number of electrons on the system island, and applies feedback as depicted in Fig. 1(a). When an electron tunnels to the island, the demon traps it with a positive charge (panels 1 and 2). Conversely, when an electron leaves the island, the demon applies a negative charge to repel further electrons that would enter the island (panels 3 and 4). The system electrodes contain a reservoir of conduction electrons whose thermal excitations provide sufficiently high energy carriers to overcome the trapping or repulsion induced by the demon, contributing heat $Q = -\Delta E$, where $\Delta E$ is the energy cost of the tunneling event. In doing so, the system entropy decreases as $\Delta S_s = Q/T_s$, where $T_s$ is the system reservoir temperature; i.e., the demon extracts information of tunneling electrons to apply feedback that causes the entropy of the system to decrease. While the configuration resembles theoretical proposals on quantum dots [25,28,29], and shares features with the Coulomb drag effect [30,31], it constitutes a genuine autonomous Maxwell’s demon where only information, not heat, is directly exchanged between the system and the demon.

Our experimental, autonomous realization of the cycle in Fig. 1(a) relies on coupling the system island capacitively to a single-electron box, a small normal metallic island connected by a tunnel junction with resistance $R_d$ to a single normal metallic lead. Here, the single-electron box undertakes the role of the demon. The resulting Hamiltonian is

$$H(n, N) = E_s(n - n_g)^2 + E_d(N - N_g)^2 + 2J(n - n_g)(N - N_g),$$

where $n$ and $N$ denote the number of electrons on the system island and the reservoir, respectively, $n_g$ is the Fermi level of the reservoir, and $J$ is the tunneling amplitude.
The interaction between the system and the demon is maximized by setting \( n_g = N_g = 0.5 \), producing the Hamiltonian \( H(n,N) = J(2n-1)(2N-1)/2 \) and energetics depicted in Fig. 1(b). We furthermore require \( eV, k_B T \ll E_s, E_d \), such that only the lowest energy states of Eq. (1) are available, where both \( n \) and \( N \) are practically limited to two possible values, 0 and 1. States \( n = 0, N = 1 \) and \( n = 1, N = 0 \) are charge neutral, both with energy \(-J/2\). Here, we refer to either of the states as “ground” or \( g \). The state \( n = 0, N = 0 \) has an overall positive charge and \( n = 1, N = 1 \) an overall negative charge. We refer to them as “charged” or \( c \), both with energy \( J/2 \). Any single tunneling event will take \( g \) to \( c \) or \( c \) to \( g \), with respective \( \Delta H_{g-c} = J - \Delta H_{c-g} \). We assume that the system is at uniform temperature \( T_s \) while the temperature of the demon is \( T_d \), such that the occupation probability distribution \( P_{n,N} \) obeys \( P_{0,1} = P_{1,0} \equiv P_g/2 \) and \( P_{0,0} = P_{1,1} \equiv P_c/2 \), with \( P_g = \Gamma_{c-g}/(\Gamma_{g-c} + \Gamma_{c-g}) \) and \( P_c = \Gamma_{g-c}/(\Gamma_{g-c} + \Gamma_{c-g}) \). Here, with notation \( J_g \equiv J \pm eV/2 \), the term \( \Gamma_{c-g} = \Gamma_s(-J_+) + \Gamma_s(-J_-) + \Gamma_c(-J) \) is the overall transition rate from \( c \) to \( g \), while \( \Gamma_{g-c} = \Gamma_s(J_+) + \Gamma_s(J_-) + \Gamma_g(J) \) is the corresponding overall transition rate from \( g \) to \( c \) as a sum of rates in the system in the direction of bias, against the bias, and the transition rate in the demon, respectively. The transition rates are

\[
\Gamma_{g/d}(\Delta E) = \frac{1}{e^2 R_{g/d}} \frac{\Delta E}{e^2} k_B T_{g/d} - 1. \tag{2}
\]

The charge current in the system is \( I = (e/2)[\Gamma_s(J_-) - \Gamma_s(J_+)]P_g + (e/2)[\Gamma_s(J_+ - J_-)]P_c \), and the total heat generation rate there is

\[
\dot{Q}_s = -[\Gamma_s(J_-) + J_+]P_g + [\Gamma_s(J_+ - J_-) + J_-]P_c, \tag{3}
\]

reflecting the fact that if the demon successfully maintains a high \( P_g \) by feedback, as in Fig. 1(b), \( \dot{Q}_s \) is negative. Similarly, the rate of heat generation in the demon is

\[
\dot{Q}_d = -J\Gamma_{d-g}(J)P_g + J\Gamma_{d-c}(-J)P_c, \tag{4}
\]

which in turn is positive as the demon applies feedback on states \( c \), as in Fig. 1(b). Consider \( T_s = T_d \equiv T \). It can be shown that when \( k_B T \cosh(J/2k_B T) < (J/4)(1 + R_d/R_s)^{-1} \), Eq. (3) (3) gives negative \( \dot{Q}_s \), i.e., cooling, within a range of \( 0 < |V_s| < |V_{\text{max}}| < 2J/e \) (see Supplemental Material for derivation [32]). The entropy of the system then decreases as \( \dot{S}_s = \dot{Q}_s/T < 0 \), seemingly against the second law, however; we still get \( \dot{S}_s = \dot{Q}_s/T = -\dot{Q}_s/T = \dot{S}_s \), resulting from Joule’s law, \( \dot{Q}_s + \dot{Q}_d = IV \).

Although energetically our device follows Joule’s law, it is the information flow between the system and the demon that permits the decrease of system entropy. The mutual information between the system and the demon is...
\[ I_m = \ln(P_{n,N}) - \ln(P_n) - \ln(P_N), \] where \( P_n \) and \( P_N \) are the occupation probabilities of \( n \) and \( N \), respectively. As \( P_{n=0} = P_{n=1} = P_{n=0} = P_{N=1} = 0.5 \), mutual information changes in a tunneling event from \( g \) to \( c \) as \( \Delta I_{m,g \rightarrow c} = \ln(P_g/P_c) \), and for \( c \rightarrow g \) as \( \Delta I_{m,c \rightarrow g} = -\Delta I_{m,g \rightarrow c} \) [6,33,34]. Tunneling events in the demon change mutual information at the rate

\[ \dot{I}_{m,d} = \ln\left(\frac{P_c}{P_g}\right) \Gamma_d(J) P_g + \ln\left(\frac{P_g}{P_c}\right) \Gamma_d(-J) P_c. \] (5)

The majority of the tunneling events in the demon are \( c \rightarrow g \) transitions, and since \( P_g > P_c \), \( \dot{I}_{m,d} \) is positive. The rate of mutual information change by the system tunneling events is \( \dot{I}_{m,s} = -\dot{I}_{m,d} \). As discussed in Ref. [34], the system heat generation satisfies \( \dot{Q_s} \geq -k_B T \dot{I}_{m,d} \), implying that the maximum amount of cooling is bound by the amount of mutual information generated by the demon. Correspondingly, generating mutual information has a thermodynamic cost for the demon as \( \dot{Q_d} \geq k_B T \dot{I}_{m,d} \).

This can also be understood in terms of the configurational entropy \( S_{\text{conf}} = -\ln[P(n,N)] \) as follows [34]: tunneling events in the demon bring the circuit from unlikely state \( c \) to the more probable state \( g \), decreasing \( S_{\text{conf}} \). At least an equivalent of heat must be dissipated to satisfy the second law. On the other hand, most of the tunneling events in the system bring the setup to a more improbable state \( c \), increasing configurational entropy. The second law then allows cooling by at most the amount of configurational entropy decreased; i.e., \( -\Delta S \leq \Delta S_{\text{conf}} \). We note that in the limit \( R_g \ll R_s \), \( P(n,N) \) follows the thermal equilibrium distribution of the demon. Then \( \ln(P_g/P_c) = J/k_B T_d \) such that \( \dot{I}_{m,d} = \dot{Q}_d/k_B T_d \) by Eqs. (4) and (5). This implies that measurement of heat generated in the demon is also a direct measurement of information extracted by the demon.

Figure 2(a) shows a scanning electron micrograph of the experimental realization of Maxwell’s demon. It was fabricated by standard electron beam lithography combined with shadow evaporation [35] of copper (normal metal) and aluminum (superconductor) metal films. Our device has the following parameters: \( E_d/k_B = 1.7 \) K, \( E_g/k_B = 810 \) mK, \( J/k_B = 350 \) mK, \( R_g = 580 \) k\( \Omega \), and \( R_d = 43 \) k\( \Omega \) (two parallel junctions each with \( \approx 85 \) k\( \Omega \) tunneling resistance).

The fully normal system and demon junctions are realized with the laterally proximized aluminum dot technique [36]. We determine the heat generated in the left (L) and right (R) lead of the system as well as the lead of the demon by measuring the respective temperatures \( T_{L,R} \), \( T_{g,R} \), and \( T_d \), as indicated in Fig. 2(a). This is achieved by reading the voltage of current-biased normal-metal-insulator-superconductor junctions; see, e.g., Ref. [37]. Finally, the leads of the system and the demon are interrupted with direct contacts to superconducting leads, which permit charge transport by Andreev processes [38] but block heat transport at low temperatures. The structure is measured in a \(^3\)He/\(^4\)He dilution refrigerator at the bath temperature of \( 40 \) mK. Details on the device fabrication and measurement configuration are given in the Supplemental Material [32].

The continuous heat generation is mediated primarily by lattice phonons that couple with the conduction electron heat bath at temperature \( T_{L,R,d} \), contributing \( \dot{Q}_{m,\text{ph}} = \Sigma \nu_m (T_{0,m} - T_m) \), where \( \Sigma \) is a material-specific constant, \( \nu_m \) is the volume of the circuit element, and \( T_{0,m} \) is the base temperature [39]. For the left and right electrodes of the system, \( \nu_{L,R} \approx 2.8 \) \( \mu m \times 70 \) nm \( \times 20 \) nm. Its island is approximately twice as large in volume. The demon has the total volume \( \nu_d \approx 4 \times 3.2 \) \( \mu m \times 150 \) nm \( \times 20 \) nm. We use \( \Sigma \approx 4 \times 10^9 \) \( \text{W m}^{-3}\text{K}^{-5} \) for Cu. The rate of electron tunneling (10\(^6\) Hz) in our device is faster than the phonon relaxation rate (10\(^4\) Hz); however, it is small compared to the inelastic electron-electron relaxation rate.
which is typically of the order of $10^9$ Hz [40], allowing the electrodes to equilibrate to an effective electron temperature $T_m$ that deviates from $T_{0,m}$. Furthermore, the temperature change caused by an individual tunneling electron is sufficiently small so that $Q_{m}/T_m$ is a good approximation for the entropy change. The temperature $T_{0,m}$ equilibrates such that the net heat generation is zero; i.e., $Q_{m} = -\dot{Q}_{ph,m}$.

The base temperature $T_{0,m}$ is measured at $n_g = N_g = 0$, where the state is Coulomb blockaded to $n = N = 0$ corresponding to the energy minimum in Eq. (1) and no heat is generated in the circuit. Figure 2(b) shows that charge current $I$ in the system modulates with $n_g$ as in a standard SET. However, when $N_g = 0.5$, the maximum measured current is smaller due to the feedback by the demon. Figure 2(c) demonstrates how at $n_g = N_g = 0.5$ the heat generated in the demon is maximized for extracting information of the transported electrons.

The main result of this Letter is presented in Fig. 3(a), showing our observation at $V = 20 \mu V = 2J/3e$ of how the system cools down and its entropy decreases.

Simultaneously, we observe how the demon, which collects the information and immediately applies a feedback to the system, generates heat as a necessary thermodynamic cost for extracting information from the system. On the other hand, Fig. 3(b) shows unchanged $T_d$ at $N_g = 0$ since the demon is effectively uncoupled from the system as its state is locked to $N = 0$. With that Coulomb blockade refrigeration [41,42] occurs when $n_g$ deviates from 0.5 by causing either the left or the right lead to cool down, but overall heat is generated and entropy is produced in the system.

Figure 4(a) shows a measurement of current (inset) and temperatures as a function of $V$ at $n_g = N_g = 0.5$. Increasing voltage bias boosts the rate of electrons passing through the system, however, at the cost of lower entropy decrease per electron. Furthermore, the risk of electrons to pass through the system without feedback control from the demon increases, in particular, via multielectron tunneling (see Supplemental Material for details [32]). Figure 4(b) compares the heat and mutual information produced by the demon, demonstrating that they differ by less than 15% for low $V$. The data shown in Fig. 4(c) show improvement of entropy decrease up to $20 \mu V$, beyond which errors in the feedback process overcome the benefit of enhanced rate of

![FIG. 3 (color online). Operation as a Maxwell’s demon and as a one-sided refrigerator. Quantities shown are $I$ (black), $\Delta T_L$ (blue), $\Delta T_R$ (green), $\Delta T_d$ (red), with parameter values $V = 20 \mu V$, $T_{0,d} = 77$ mK, and $T_{0,m} = 55$ mK. (a) Measurement at $N_g = 0.5$ (Maxwell’s demon). Both $T_L$ and $T_R$ decrease, indicating overall cooling of the system. This is justified by the mutual information transfer between the system and the demon, which in turn generates heat in the demon, observed as elevated $T_d$. (b) Measurement at $N_g = 0$ (SET refrigeration [41,42]). Either $\Delta T_L$ or $\Delta T_R$ can be negative, however, not simultaneously: overall heat is generated in the system. Measured data (symbols) are shown on the left and numerically obtained predictions (lines) on the right. (c) Energetics at different operation points, indicated as numbers in (a) and (b). At the operation point 1, the demon is interacting with the system as in Fig. 1(b). At operation points 2–4, the demon is inactive.](image)

![FIG. 4 (color online). Bias dependence. Here, $n_g = 0.5$, $N_g = 0.5$, and $T_{0,d} = 55$ mK. The data points (symbols) are obtained by averaging over 210 repetitions. (a) $\Delta T_L$ (blue squares), $\Delta T_R$ (green circles), and $\Delta T_d$ (red diamonds) with their respective prediction with $T_{0,d} = 77$ mK (dashed lines) and $T_{0,m} = 62$ mK (solid lines). Inset: $I$ in the same measurement. Applying voltage increases the number of electrons passing through the system and in turn the information flow between the system and the demon. This is observed as increased $T_d$. (b) Numerical comparison between $\dot{Q}_d/k_B T_d$ and $I_{m,d}$, demonstrating that the two quantities match. (c) Enlarged view of the measured $\Delta T_L$ (blue squares) and $\Delta T_R$ (green circles). Increasing voltage bias further enhances the entropy decrease in the system up to about $\pm 20 \mu V$. The model assumes a perfectly symmetric system and therefore predicts equal $\Delta T_L$ and $\Delta T_R$ with the fit $T_{0,d} = 62$ mK (solid line).](image)
electron injection. At this voltage, the cooling power on the system is estimated to be $-\dot{Q}_d \approx 6$ aW, while the heat dissipation in the demon is $\dot{Q}_d \approx 19$ aW. Based on the heat generation, the mutual information production rate by the demon is then $\dot{I}_m \approx 25 \times 10^6$ Hz. The current is $I \approx 600$ fA; i.e., $\sim 4 \times 10^6$ electrons cross the system per second. Should successful feedback be performed for every electron, the heat generated by the demon would be $I \times 2J/e \approx 36$ aW. Experimentally, we observe $\approx 52\%$ of this value; i.e., this fraction of the electrons transported through the system are successfully feedback controlled by the demon. For efficiency at maximal cooling power, $-\dot{Q}_d/IV$, we then get $\approx 0.56$.

In conclusion, we have realized and demonstrated experimentally a physically transparent autonomous Maxwell’s demon on a chip, based on coupled single-electron circuits undergoing tunneling events in a self-controlled manner. The demon acts on the system to decrease its entropy, observed as a temperature drop. The configuration allows one to measure the effect of the demon on the system, as well as to measure the thermodynamics of the demon itself. The device presented here demonstrates how information is transferred from the system to the demon, leading to heat generation in the demon in an amount that corresponds to the rate of information transfer. This setup constitutes a step towards autonomous information-powered nanodevices.
