Distorted representation of one’s own body is a diagnostic criterion and core psychopathology of disorders such as anorexia nervosa and body dysmorphic disorder. Previous literature has raised the possibility of utilising physical activity intervention (PI) as a treatment option for individuals suffering from poor body satisfaction, which is traditionally regarded as a systematic distortion in “body image.” In this systematic review, conducted according to the PRISMA statement, the evidence on effectiveness of PI on body representation outcomes is synthesised. We provide an update of 34 longitudinal studies evaluating the effectiveness of different types of PIs on body representation. No systematic risk of bias within or across studies were identified. The reviewed studies show that the implementation of structured PIs may be efficacious in increasing individuals’ satisfaction of their own body, and thus improving their subjective body image related assessments. However, there is no clear evidence regarding an additional or interactive effect of PI when implemented in conjunction with established treatments for clinical populations. We argue for theoretically sound, mechanism-oriented, multimethod approaches to future investigations on body image disturbance. Specifically, we highlight the need to consider expanding the theoretical framework for the investigation of body representation disturbances to include further body representations besides body image.

Keywords: body image, body representation, physical activity, eating disorders, body dysmorphic disorders

INTRODUCTION

Disturbances in body representation have been identified as the crux of many debilitating psychiatric disorders, such as body dysmorphic disorder (1), body integrity identity disorder (2), somatoparaphrenia (3), and asomatognosia (4). It has also been proposed as a core psychopathology of eating disorders [e.g., (4–9)]—especially in anorexia and bulimia nervosa. Heightened body dissatisfaction has been interpreted as a predisposition indicator in subclinical populations.

Influence of Physical Activity Interventions on Body Representation: A Systematic Review

Distorted representation of one’s own body is a diagnostic criterion and core psychopathology of disorders such as anorexia nervosa and body dysmorphic disorder. Previous literature has raised the possibility of utilising physical activity intervention (PI) as a treatment option for individuals suffering from poor body satisfaction, which is traditionally regarded as a systematic distortion in “body image.” In this systematic review, conducted according to the PRISMA statement, the evidence on effectiveness of PI on body representation outcomes is synthesised. We provide an update of 34 longitudinal studies evaluating the effectiveness of different types of PIs on body representation. No systematic risk of bias within or across studies were identified. The reviewed studies show that the implementation of structured PIs may be efficacious in increasing individuals’ satisfaction of their own body, and thus improving their subjective body image related assessments. However, there is no clear evidence regarding an additional or interactive effect of PI when implemented in conjunction with established treatments for clinical populations. We argue for theoretically sound, mechanism-oriented, multimethod approaches to future investigations on body image disturbance. Specifically, we highlight the need to consider expanding the theoretical framework for the investigation of body representation disturbances to include further body representations besides body image.

Keywords: body image, body representation, physical activity, eating disorders, body dysmorphic disorders

INTRODUCTION

Disturbances in body representation have been identified as the crux of many debilitating psychiatric disorders, such as body dysmorphic disorder (1), body integrity identity disorder (2), somatoparaphrenia (3), and asomatognosia (4). It has also been proposed as a core psychopathology of eating disorders [e.g., (4–9)]—especially in anorexia and bulimia nervosa. Heightened body dissatisfaction has been interpreted as a predisposition indicator in subclinical populations.
Individuals with body image concerns are reportedly more vulnerable to developing eating and dieting pathologies (10–13). As yet, however, mechanisms of change in body representation are still poorly understood, limiting mechanism-oriented interventions for prevention and treatment of disturbed body representation.

Previous literature has suggested that regular physical activity has beneficial effects on the physical health of the body, as well as a significant impact on the level of satisfaction with which the body is perceived [e.g., (14–16)]. This is surprising, insofar as cross-sectional studies in individuals with high levels of physical activity suggest decreased rather than increased body satisfaction (17). However, it is important to note that there has been little critical appraisal of the existing studies. Previous systematic reviews and meta-analyses on the topic of physical activity and its potential interactions with body satisfaction have been conducted from an outcome-centric perspective [e.g., (14, 15, 18–20)]—focusing on evaluating the effectiveness of physical activity as an intervention for the improvement of individuals’ body satisfaction—with an emphasis on the affective and cognitive aspects (i.e., body image). Nevertheless, the question of which potential mechanisms might be responsible for the apparent shift in body image after the introduction of physical activity has not been inadequately addressed.

Despite the lack of a unified consensus on its exact nature, the term body image has been widely used in research across psychology, neuroscience, and psychiatry. Body image can roughly be characterised as the conscious, predominantly visual, mental representation of one’s own body, which in turn provides a basis upon which perceptual, cognitive, and affective attitudes toward the body are assigned (21, 22). However, it is important to note that the current literature largely concurs on the use of the term body image as a measure of body satisfaction—in that body image as an outcome measure is interpreted as the degree with which individuals are satisfied with various aspects of themselves that is influenced by the visual aspect of their body (e.g., appraisal of body shape information). In this review, we therefore adopt the term body representation when referring to the broad range of mental representations of one’s own body, whereas body image only refers to cognitive-affective appraisal of the body. The fact that body image investigations in health research has so far been conducted from an almost exclusively perceptual-affective perspective is worth discussing.

Longo (23) argued that higher level representations of the body are unlikely to emerge from abstract cognition alone. Rather, they are constructed through the interplay of multiple distinct body representations. Not only do individuals have immediate knowledge of their body from within (i.e., bodily awareness through interoception), they are also able to objectively reflect on their own body from an external perspective, in the same way that external objects are cognitively assessed (with regards to their shape, size, location, aesthetics, et cetera). Relying on neuroscientific evidence, Longo’s framework of body perception consists of multiple distinct body representations that are informed by different sensory modalities and can be arranged along two orthogonal axes: explicit vs. implicit & perceptual vs. conceptual. However, most empirical data concerning body image has been based on self-report or visual body size judgments, which effectively leads to the underrepresentation of other somatically driven/sensory inputs when considering the potential mechanism underlying the concept of body image (24). Although these subcomponents of body representation have been demonstrated to have distinct underpinning neural networks [see (25) for review], the mechanisms responsible for the development and regulation of these subcomponents are still very much unexplored (e.g., the idea that body satisfaction, or the lack thereof, could be socially and/or somatically driven—or the product of their interactions).

As such, it is not at all clear why the body image should remain the sole focal point when investigating how individuals mentally represent their own body, and the potential distortions therein.

In this systematic review, we aim to synthesise existing literature investigating longitudinal interaction between physical activity and body image. Our purpose is to synthesise the empirical evidence from previous studies with a focus on effects, broader potential, and eventual impact mechanisms of physical activity on body representation. Specifically, our research questions were:

i. Are there systematic effects of physical activity on body representation?

ii. Are previous studies informative with regard to prevention or treatment of sub-clinical or clinically relevant body image disturbance?

iii. Are there specific mechanisms of how long-term engagement in structured physical activity influence the dynamics of individuals’ body representations?

METHOD

The systematic review process was conducted according to the PRISMA statement (26). Methods of analysis and inclusion criteria were specified in advance and documented in a protocol.

Literature Search

Studies were identified via searching the following electronic databases: PubMed, Web of Science and SPORTDiscus. The search was weekly updated until January 2020.

The specific search terms are as follows: (“body image” OR “body representation” OR “body dissatisfaction” OR “body satisfaction” OR “body image disturbance”) AND (“physical activity” OR “physical exercise” OR “exercise intervention” OR “endurance training” OR “exercise training” OR “exercise intervention” OR “aerobic exercise” OR “aerobic training” OR “anaerobic exercise” OR “anaerobic training” OR “motor activity” OR “resistance training” OR “resistance exercise” OR “strength training” OR “weight training” OR “weightlifting” OR “cardio training” OR “cardio” OR “athletic sports” OR “exercise program” OR “fitness training” OR “cardiovascular training” OR “interval training” OR “intermittent training” OR “interval exercise” OR “intermittent exercise” OR “sprint training” OR “sprint exercise” OR “high intensity interval training” OR “high intensity interval exercise” OR “moderate intensity training” OR...
“moderate intensity exercise” OR “exercise/psychology” OR “exercise therapy/methods” OR “resistance training/methods”). Additionally, reference lists of included articles were hand searched.

**Eligibility Criteria and Study Selection**

Each step of the eligibility assessment was performed independently by two reviewers according to the PICOS criteria (27). Only articles in English were considered. Studies had to fulfil the following criteria:

- **Population**: a sample of adult participants,
- **Intervention**: include a longitudinal physical activity intervention (PI; no lifestyle counselling; specific targeting of body image/ body representation not compulsory),
- **Comparison/Control**: include a validated measure of body image/ body representation, a control group was not required,
- **Outcome**: at least one pre & post measurement of a validated self-report or experimental body image/body representation measure, and
- **Study Type**: published as a peer-reviewed original article.

Exclusion criteria were as follows:

i. samples younger than 18 years old, and
ii. no inference statistics performed.

The first author (DS) applied the search terms to three databases, extracted the search results and removed duplicates. DS and LW screened titles to identify relevant records. Abstracts and full texts of the identified records were subsequently screened by DS and SB. All studies included in the qualitative synthesis were rated according to the eligibility criteria by DS and SB. Interrater reliability between DS and LW for title screening was good ($\kappa = 0.61; 94.2\%$ agreement). Articles were included in the full-text screening if one reviewer rated it as a potential match. Interrater reliability between DS and SB for the subsequent steps was very good ($\kappa = 1.0$ for abstract screening; $\kappa = 0.94$ for full-text screening). Disagreements between the reviewers were solved by discussion and, when in doubt, articles were included. DS extracted relevant data from the included studies (i.e., sample characteristics, PI types and dosage, measure of fitness level, measures of body composition, measures of body image/body representation, and results).

**Risk of Bias in Individual Studies**

To assess the risk of bias in individual studies, DS and SB conducted a quality rating. The Qualitative Assessment Tool for Quantitative Studies by the Effective Public Health Practice Project (28, 29) is recommended by the Cochrane Handbook for Systematic Reviews of Interventions to be used for assessing any quantitative study design (30) and was judged a suitable tool for systematic reviews of effectiveness (31). The tool consists of component ratings for the following categories: selection bias, study design, confounders, blinding, data collection methods, and withdrawals and dropouts. Components were rated according to the accompanying dictionary. Studies received ratings of either “strong”, “moderate”, or “weak” for each category. A global rating was assigned at the end of the process via the summarisation of the number of categories rated as “weak”. Disagreements between the reviewers were solved by discussion.

**RESULTS**

**Study Selection**

The searches yielded a total of 3,318 results. Duplicates were discarded ($n = 602$), leaving 2,716 records for title and abstract screening. During this process, 2,659 studies were discarded, and the remaining 57 studies were identified for full-text analysis. Subsequently, 34 studies were included in the systematic review. For the PRISMA flow chart, see Figure 1.

**Study Quality**

The overall study quality within the current review showed a slight majority for “weak” (55.88%; $n = 19$), followed by “moderate” (41.17%; $n = 14$). Only 1 study (2.94%) included in the review qualified for the global “strong” rating. The detailed components ratings are included in Table 1.

Notably, included studies only received weak ($n = 26$) and moderate ($n = 8$) ratings for the selection bias category. The main reason for depreciation was the recruitment in sports classes or from community samples; thus producing a selection bias favouring highly motivated, sports-oriented participants. In the same vein, most studies qualified for moderate rating in the study design category ($n = 27$). This is due to the lack of randomisation in the selection as well as group allocation process, as participants often conducted the PI of their own design. This limits explanatory power regarding general recommendations of effective types of training. To summarise, there is a possibility for risk of bias in the studies included in the current review.

**Study Characteristics**

The study characteristics of included studies are detailed in Table 1. All studies employed a longitudinal design, as defined by the inclusion criteria. Of the total 34, 6 studies were described as quasi-experimental. Twenty-three studies included control groups in their experimental design, while the remaining 11 did not. Within the 23 controlled studies, 18 studies included “no intervention” comparison groups, while the remaining 5 studies included participants who performed low to moderate exercise as controls. Eight studies included clinical and/or sub-clinical groups. The remaining 26 studies had healthy samples. Eleven studies aimed to compare different types of PI and their impact on body image/body representation of participants. Most studies ($n = 27$) did not have a randomised participant selection and/or group allocation process.

**Physical Activity Interventions**

The most commonly investigated types of PI were weight/strength training ($n = 14$), as well as aerobics/cardiovascular training ($n = 13$). Three studies implemented the combination of
both types as a singular intervention. Dancing (n = 3) was also investigated. Other PIs included walking, running, swimming, cycling, pilates, hydrogymnastics, yoga, fascial fitness, and functional training. The mean length of time for the implementation of the PI was 13.29 (SD = 8.45) weeks, with the maximum of 52 weeks (1 year) and the minimum of 2 weeks. The median for PI duration was 12 weeks.

VO2max was used as a measure of fitness in 9 studies. Eleven studies conducted strength tests as a marker of fitness level (i.e., variations of maximum repetition test). Heart rate was also measured as a marker of fitness level (n = 4). Twelve studies did not report any measure of physical fitness.

Outcome Measures

Studies were homogeneous in terms of the operationalisation of body image/body representation measures. Almost all studies exclusively implemented validated questionnaires assessing body image. Only 3 studies additionally implemented more visual-oriented measures (i.e., Stunkard Scale of Silhouette, Figure Rating Scale)—though nevertheless still affective/subjective in nature. No study used experimental assessments of body representation (e.g., depictive/metric body size and visual estimation tasks). As such, the domains of visual, tactile and affordance perception of body representation were not at all investigated.

The most commonly employed scales were MBSRQ (Multidimensional Body Self-Relations Questionnaire; (66) and PSPP (Physical Self-Perception Profile; (67) at 23.53% (n = 8) each. The Body Cathexis Scale was also frequently implemented in earlier studies (n = 7; 20.59%; (68).

Systematic Effects of PI on Body Representation

PI was considered effective if significant improvement in body representation measures was reported at post-test among the intervention group, relative to the control group. The overall results are as follows: 5 studies (14.71%) observed no significant improvement in both control and PI groups across all body image measures; 3 studies (8.82%) observed significant improvement in both control and PI groups across all body image measures; 10 studies (29.41%) reported significant improvement in PI group across all body image measures; 16 studies (47.06%) reported partial significance effect in PI groups (i.e., not all improvement in scores measured in the subscales of the implemented questionnaires reached significance).

However, due to the low number of clinical and sub-clinical studies (n = 8) included in this systematic review, we cannot reliably synthesise significant evidence with regard to utilising long-term PI (structured or otherwise) as a treatment measure for clinically relevant groups.
| Study     | Sample characteristics | n   | Physical activity intervention & dosage | Measure of fitness level | Measure of body composition | Measure of body image/representation | Main findings                                                                 | Quality rating: | Strong | Moderate | Weak | Selection bias | Study design | Confounders | Blinding | Data collection methods | Withdrawal and dropouts |

- Significant improvements in Physical Condition and Body Attractiveness.
- There were no significant differences between PI groups for both short and long-term results.

※ There were no significant differences between PI groups for both short and long-term results.

Effects on Body Attractiveness while the structured group showed significant improvements in Physical Condition and Body Attractiveness.

Although there were no significant differences between PI groups for both short and long-term results, the structured group showed significant improvements in Physical Condition and Body Attractiveness.

- All groups revealed no statistical improvement in PSPP scores post-test.

- Showed significant improvement between baseline and 6 months post PI in Perception of Physical Appearance, Functionality and Total Physical Self-Concept.

- No significant differences were observed over time.

Control Group
- Appearance Evaluation and Body Areas Satisfaction subscales of MBSRQ significantly decreased during no PI condition.

- Appearance Evaluation and Body Areas Satisfaction subscales of MBSRQ were unaffected by PI.

PI Group
- Significant improvement in MBSRQ scores was observed post PI.

Control Group
- No significant changes in MBSRQ scores were reported post-test.

| Physical activity intervention & dosage | Measure of fitness level | Measure of body composition | Measure of body image/representation | Main findings | Quality rating: |
|----------------------------------------|--------------------------|----------------------------|-------------------------------------|--------------|----------------|
| Aerobic & resistance training          | Waist & hip circumferences | PSPP PI and Control Groups | ●            | ○              |

- PI group showed significant increases post PI for all PSPP subscale scores except for Perceived Body Attractiveness as compared to control group.
Mechanisms Underpinning the Interplay Between PI and Body Representation

All studies included neither explicitly addressed/proposed a form of a mechanistic interplay between PI and body representation, nor provided evidence to support one. As such, the question of which potential mechanisms might be responsible for the apparent shift in body representation after the introduction of physical activity remain inadequately addressed.

DISCUSSION

In this systematic review, we synthesised the empirical findings from longitudinal intervention studies on effects of structured PI on body representation. Overall, the studies suggest that the implementation of structured PI is associated with improved body image. Effects on other body representations were not investigated. To our knowledge, this review is the first to demonstrate such an effect in longitudinal settings. The effectiveness of these interventions seems promising for future research and possible development of prevention interventions. However, we argue that due to the quality of existing studies, further research is highly necessary to investigate whether the positive effects of PI can be generalised across healthy (active or sedentary), sub-clinical as well as clinical populations, and to capture a more complete sense of body representations that allows for exploring potential mechanisms of change.

Based on the evidence available, PI can be cautiously regarded as a potentially effective option regarding body image related outcomes. Notably, the studies included in the review examined predominantly volunteer groups (i.e., people who were generally open to the idea of engaging in physical activity), even if they were previously sedentary. It remains unclear whether positive effects of PI would also generalise to the voluntarily sedentary population who are physical-activity-reluctant. From a clinical perspective, these groups would be very relevant, since they are at higher risk for cardiovascular diseases and obesity. Thus, from the current studies, it remains unclear whether positive effects of PI can be generalised across healthy (active or sedentary) and clinical populations, and to capture a more complete sense of body representations that allows for exploring potential mechanisms of change.

Based on our systematic review, it would not be responsible to simply conclude that PI might be a promising treatment option for sub-clinical and/or clinical populations whose core psychopathology is centred around body dissatisfaction and distorted representation of one's own body. Despite the fact that a general improvement in measures of body representations can be observed, the percentage of clinical and sub-clinical studies included within the systematic review is too low to draw such a conclusion (23.53%). Additionally, there is no clear evidence regarding an additional or interactive effect of PI when implemented in conjunction with established treatments for clinical populations. More importantly, a previous meta-analytic review of stand-alone interventions to improve body image by Alleva and colleague (18) has provided evidence which cautioned against discussing physical activity with patients, as it was significantly associated with poorer body image.
image outcomes. The meta-analysis proposed that by discussing physical activity as an intervention, patients may inadvertently have their attention drawn to their own weight and appearance, as well as the associated societal standards for physical fitness and physical attractiveness. Further, it was also not reported to be significantly associated with larger intervention effects on body image. Until the literature on the underlying mechanism between physical activity and body representation is further investigated, physical activity-related interventions targeting body image/representation should therefore be exclusively kept to psychologically healthy populations or be closely embedded in an overall treatment concept.

Notably, objective improvements in bodily composition and physical fitness brought about by PI are inconsistently related to changes in body image. This is surprising, insofar as people typically assume that their body image is based on an objective evaluation and comparison of their body. Instead, it appears that complex appraisal processes, eventually involving perceived improvements in physical capacities or more intense somatosensory experiences during PI may play a more important role. PI interventions could serve to improve body image/body representation by allowing individuals to redirect their attention more toward the functionality of their body and less on their appearance, or by increasing their sense of physical efficacy (69, 70). In this sense, the previous literature supports the need for a comprehensive, multisensory assessment of body representation as suggested by the Longo framework.

Strengths and Methodological Considerations

To our knowledge, this review is the first to provide a comprehensive systematic review on the topic of the longitudinal interactions between PI and body representation—the definition of which we have updated and adapted to fit the more complex theories and discussions which have arisen over the years.

Methodological limitations of this review arise from our study selection process as well as from the included studies. As we only searched for published results, a publication bias towards significant effects cannot be excluded. Further, as terminology in the field is very heterogeneous, it is possible that despite our broad search strategy, a few relevant articles may have been missed. Notably, some of the included studies had small sample sizes and may have been underpowered. The current systematic review is also potentially limited by biases within studies. Although nonsystematic risk of bias across or within studies were identified, 97% of the included studies were considered at risk with regards to selection bias and study design. More importantly, all studies are lacking in the variety of validated outcome measures. Only self-report questionnaires were implemented, and the main component of body image addressed here was body satisfaction or the lack thereof. Additional visual scales implemented were used to measure the disparity between participants’ subjective ideal versus actual body shapes, which, once again, only measured participants’ attitudinal/conceptual issues of their own body image. Moreover, the two studies whose results also reported long-term effects of PI on body image were shown to be in direct contradiction (40, 50). One possible explanation for the contrasting results might be the difference in the type and dosage of the PIs implemented. As such, it remains unclear whether PI-induced body image improvement is indeed sustainable.

Perspectives and Future Directions

Our systematic review revealed that evidence on PI as a means to change body representation is still limited. A major challenge for future research is not only to reduce selection bias in the investigated samples, but also to explore potential mechanisms of body image improvement via PI through adopting a broader perspective on body representation. Based on our review, we argue for a more comprehensive view that takes various sources of information about the body into account (71, 72). In pursuit of a mechanism-oriented intervention, it is imperative to have a solid grasp on the understanding of how body image/body representation are constructed and which aspects drive changes in how individuals mentally represent their body.

The assessment of multisensory body representation is challenging. However, an increasing number of experimental paradigms have been developed in recent years to assess such concepts as: interoception [e.g., (73–75)], implicit knowledge of body dimensions (76–78) and multisensory integration (24). Despite reports of potentially disturbed multisensory integration and interoception in eating disorders (24, 79, 80), these measures have so far been largely neglected in clinical research. We expect that a broader use and further development of these methods in body representation assessment could give rise to a more informed understanding of the mechanisms of disturbed body representation and its malleability.

To this end, it is important to undertake future research on (i) identifying valid tasks to investigate different body representations (e.g., through combining actual body measures with tasks assessing body size estimation, interoceptive abilities or affordance estimates with questionnaires assessing cognitive-affective appraisal of the body), and (ii) investigate the malleability and interactions between different body representations.

AUTHOR CONTRIBUTIONS

DS, KG, SB, SZ, and AT conceptualized the project. DS, SB, and L-MW performed the literature review. DS wrote the first draft of the manuscript. SB, KG, HW, and AT critically reviewed the manuscript with respect to their areas of expertise: body image and eating disorders (KG, SB, SZ); philosophy and cognitive science of body perception (HW); and sports science (AT).

FUNDING

This review was supported by a grant from the intramural graduate school "iReAct" of the University and the University Hospital Tübingen. We acknowledge support by Open Access Publishing Fund of the University Tübingen.
