Abstract. We introduce a new method, based on the recently developed random tensor theory, for studying the $p$-spin glass model with non-Gaussian, correlated disorder. Using a suitable generalization of Gurau’s theorem on the universality of the large $N$ limit of the $p$-unitary ensemble of random tensors, we exhibit an infinite family of such non-Gaussian distributions which leads to the same low temperature phase as the Gaussian distribution. While this result is easy to show (and well known) for uncorrelated disorder, its robustness with respect to strong quenched correlations is surprising. We show in detail how the critical temperature is renormalized by these correlations. We close with speculation on possible applications of random tensor theory to finite-range spin glass models.

Keywords: disordered systems (theory), spin glasses (theory), random matrix theory and extensions

ArXiv ePrint: 1206.5539
1. Introduction

It is well known that the phase diagram of the $p$-spin glass model [1, 2] does not depend on the details of the disorder distributions, in the following sense: if $J_{i_1\cdots i_p}$ denotes a set of independent and identically distributed $p$-valent couplings between sites $i_1 \cdots i_p$, a non-quadratic potential $V(J_{i_1\cdots i_p})$ in the coupling distribution

$$\prod_{i_1\cdots i_p} dJ_{i_1\cdots i_p} e^{-J_{i_1\cdots i_p}^2/\sigma^2+V(J_{i_1\cdots i_p})}$$

is irrelevant in the thermodynamic limit. That a similar result would hold for correlated disorder distributions, with terms such as

$$\sum_{\{i,j\}} J_{i_1i_2i_3}J_{i_1j_2j_3}J_{j_1j_2j_3}J_{j_1i_2i_3},$$

in the potential, is much less obvious. In fact, to our knowledge, no analytic framework for dealing with such correlated, non-Gaussian disorder has been reported so far. Since disorder correlations are to be expected in actual physical systems, understanding their effect is an important problem.

In this work we exhibit an infinite class of non-Gaussian terms of the kind (2) such that (i) the thermodynamic limit $N \to \infty$ is exactly soluble, and (ii) the spin glass phase has the same structure as for uncorrelated disorder, except for a renormalization of the critical temperature. This provides the first general result on spin glasses with strongly correlated disorder.

Our approach is based on new results in random tensor theory. A natural generalization of random matrices—random tensors—have recently been shown to possess a large $N$ limit [3] dominated by a few, well-identified ‘melonic’ graphs (the tensor equivalent of ’t Hooft’s planar graphs in matrix theory [4]). Furthermore, the melonic family can actually be resummed exactly, and turns out to exhibit interesting critical and multicritical behavior [5]. These results have not been applied to spin glass problems previously, and our hope in this work is to convey that random tensors are potentially powerful tools for spin glass theory, just like random matrices [6].

doi:10.1088/1742-5468/2013/02/L02003
Universality in $p$-spin glasses with correlated disorder

From the perspective of random tensor theory, the quenched couplings of spin glasses with $p$-spin interactions are non-Gaussian rank-$p$ random tensors. The behavior of such tensors in the large $N$ limit has been investigated in [7, 8], with a striking conclusion: in a suitable ensemble with $p$-unitary symmetry (more details are given in the text), this limit is \textit{universally Gaussian}. This means that, in this ensemble, in the large $N$ limit the sole effect of the self-interactions of large tensors is to dress the propagator. Here, we show how this result can be generalized to include interactions between tensors and spin variables, and thus obtain the aforementioned universality result.

This work is organized as follows. We first recall the Hamiltonian for $p$-spin models and insist on the need for a correlated disorder. Then, we recall the relevant properties of large random tensors in the $p$-unitary ensemble. This enables us to show how non-Gaussian, correlated, quenched variables can be integrated exactly in the large $N$ (thermodynamic) limit, yielding our universality theorem. We conclude with a few words on the possible relevance of tensor techniques for finite-range $p$-spin glasses.

1.1. $p$-spin glass models

We consider a $p$-spin Hamiltonian [1, 2]

$$ H_J(S) = - \sum_{1 \leq i_1 \cdots i_p \leq N} J_{i_1 \cdots i_p} S_{i_1} \cdots S_{i_p} + c.c. \tag{3} $$

where $J_{i_1 \cdots i_p}$ is a complex tensor describing the couplings and $S = (S_i)_{1 \leq i \leq N}$ is a set of real spins with lattice index $i$, weighted by a (normalized) probability measure $d\Omega(S)$ such that

$$ \int d\Omega(S) \sum_{i=1}^N S_i^2 = O(N). \tag{4} $$

This includes in particular Ising [1] and spherical [2] spins.

When the couplings are Gaussianly distributed, it is well known that such $p$-spin glass models exhibit replica symmetry breaking in the low temperature phase [2, 11, 12] and have a dynamical transition at a higher temperature where a large number of metastable states (growing exponentially with $N$) dominates the free energy landscape [13, 14]; their relevance is conjectured to extend to structural glasses [15]. These results extend easily to the case of independent and identically distributed (i.i.d.) couplings: all terms of order higher than 2 in $J_{i_1 \cdots i_p}$ and $\overline{J}_{i_1 \cdots i_p}$ in the measure on $(J, \overline{J})$ are irrelevant in the thermodynamic limit $N \to \infty$.

In this work we aim to study a family of \textit{correlated} non-Gaussian measures on the disorder. Physically, randomness of the couplings comes from randomness of the positions of the spins, and in general we should not expect the couplings between different sets of $p$ spins to be independent (for instance due to the geometric relations between the positions of the spins). One should therefore perturb the Gaussian distribution (with covariance $\sigma^2$)

3 The use of complex rather than real tensors is motivated by purely technical convenience and does not change the physics in any way.

4 It is also possible to include Potts or vector spins coupled according to some fixed multi-linear map.

doi:10.1088/1742-5468/2013/02/L02003
on the couplings with a polynomial $V(J, \overline{J})$. The quenched free energy is given by

$$[F(J, \overline{J})] = \frac{\int dJ d\overline{J} e^{-Np^{-1}(J \cdot \overline{J}/\sigma^2 + V(J, \overline{J}))} F'(J, \overline{J})}{\int dJ d\overline{J} e^{-Np^{-1}(J \cdot \overline{J}/\sigma^2 + V(J, \overline{J}))}},$$

with

$$- \beta F(J, \overline{J}) = \ln \int d\Omega(S) e^{-\beta H_J(S)},$$

and $J \cdot \overline{J}$ is shorthand for $\sum_{j_1 \ldots j_p} J_{j_1 \ldots j_p} \overline{J}_{j_1 \ldots j_p}$.

The evaluation of $[F]$ for a generic potential $V$ is of course a completely open problem. However, the theory of large random tensors provides an exact calculation for an infinite family of potentials satisfying a particular kind of invariance.

### 1.2. Large random tensors

We now review the relevant properties of large random tensors discovered in [3, 5, 7]. The first obvious observation is that, unlike symmetric/Hermitian matrices, tensors cannot be diagonalized. Hence, a key concept in random matrix theory, the eigenvalue distribution, does not carry over to the case of higher rank. It turns out however that this fact does not preclude the development of random tensor theory, which in fact relies on the identification of an ensemble with suitable symmetry properties.

One such ensemble of tensors—indeed the only one identified so far—is the $p$-unitary ensemble, defined as follows. Consider a rank-$p$ complex tensor in $N$ dimensions $J$, with components $J_{i_1 \ldots i_p}$ in a fixed basis, and for each set of $p$ unitary matrices $U^{(1)}$ to $U^{(p)}$, define

$$J'_{i_1 \ldots i_p} = \sum_{j_1 \ldots j_p} U^{(1)}_{i_1 j_1} \cdots U^{(p)}_{i_p j_p} J_{j_1 \ldots j_p}.$$

Then we say that a function $V(J, \overline{J})$ of $J$ and its complex conjugate $\overline{J}$ is a $p$-unitary invariant if

$$V(J', \overline{J'}) = V(J, \overline{J}).$$

The set of $p$-unitary invariants is conveniently parameterized by $p$-bubbles $B$, that is $p$-valent bipartite connected graphs with edges colored by numbers between 1 and $p$, such that each ‘color’ is incident exactly once to each vertex; see figure 1. A bubble represents an invariant denoted as $\text{tr}_B(J, \overline{J})$, by associating a tensor $J$ with each ‘white’ vertex of $B$ and a conjugate $\overline{J}$ to each ‘black’ vertex, and contracting their $k$th indices along the edges colored with $k$. By the fundamental theorem of classical invariants of $U(N)$ (see for instance [9]), a general $p$-unitary invariant can be expanded as

$$V(J, \overline{J}) = \sum_B t_B \text{tr}_B(J, \overline{J}),$$

where the $t_B$ are coupling constants.

---

5 The corresponding symmetry group is known as the external tensor product of $p$ copies of $U(N)$. 

**doi:**10.1088/1742-5468/2013/02/L02003
Universality in $p$-spin glasses with correlated disorder

Figure 1. Some $p$-bubbles at $p = 3$. Up to color relabeling, there is a single bubble with four vertices (on the left), whose invariant is $\sum_{\{i,j\}} J_{i_1i_2i_3i_4}J_{i_1j_2j_3j_4}J_{j_1i_2i_3}$. But there exist different bubbles with six vertices (the three on the right).

For a given invariant potential $V(J,\bar{J})$, we define the average of $f(J,\bar{J})$ over $J$ by

$$\left[f(J,\bar{J})\right] = \frac{\int dJ \, d\bar{J} \, e^{-Np^{-1}(J \cdot \bar{J}/\sigma^2 + V(J,\bar{J}))} f(J,\bar{J})}{\int dJ \, d\bar{J} \, e^{-Np^{-1}(J \cdot \bar{J}/\sigma^2 + V(J,\bar{J}))}}.$$

(10)

The Feynman diagrammatic expansion of these quantities involves $(p+1)$-colored bipartite graphs, made of $p$-bubbles connected together via extra lines with color ‘0’ incident on each vertex and corresponding to the propagator $\sigma^2$ in (10).

The following results concerning the large $N$ limit of (10) have been proved:

- The Feynman expansion is dominated in the large $N$ limit by a simple class of graphs, called melonic graphs, which generalize 't Hooft’s planar graphs [3]. Intuitively, a $(p+1)$-colored graph is melonic if it can be built from recursive insertions on any line of two vertices connected together by $p$ lines, as in figure 2.
- The large $N$ limit is Gaussian, in the sense that up to subleading corrections in $1/N$,

$$\left[\text{tr}_B(J,\bar{J})\right] = NG_2^{\sqrt{|B|}/2},$$

(11)

where $|B|$ is the number of vertices of the bubble $B$ and $G_2 = [J \cdot \bar{J}] / N$ is the dressed propagator depending on the potential $V$ [7].
- The following Schwinger–Dyson equation holds in the $N \to \infty$ limit [8]:

$$\frac{[J \cdot \bar{J}]}{\sigma^2 N} + \sum_B t_B \frac{|B|}{2} \frac{[\text{tr}_B(J,\bar{J})]}{N} = 1.$$

(12)

The first result implies that all non-melonic bubbles $B$ in the potential drop out in the large $N$ limit, and therefore we can restrict the sum in (9) to melonic bubbles (and hence hereafter $B$ will always denote a melonic bubble). In figure 1, all bubbles are melonic except the non-planar one on the right.

The second result has been coined the universality property of the $p$-unitary ensemble of random tensors, and can be seen as a non-trivial generalization of the central limit theorem. Its origin is that there is only one way to dress a melonic bubble $B$ with propagators in a melonic way, which happens to correspond to Gaussian contractions. This feature is specific to tensors and does not hold for random matrices. In a way, this work can be read as the physics counterpart of this surprising mathematical result. We refer the reader to the review [10] and to the original papers for more details on random tensor theory.

doi:10.1088/1742-5468/2013/02/L02003
1.3. Universality in the couplings

Let us now come back to spin glasses. Following the standard recipe for computing quenched quantities [17], we consider the averaged replicated partition function

$$[Z^n] = \int \prod_{a=1}^n d\Omega(S^a) e^{-\beta H_{\text{eff}}(\{S^a\})},$$

(13)

where $a$ is the replica index and the effective Hamiltonian is defined by

$$e^{-\beta H_{\text{eff}}(\{S^a\})} = \left[e^{-\beta \sum_{a=1}^n H_J(S^a)}\right].$$

(14)

In diagrammatic language, $H_{\text{eff}}$ is given by the sum over all connected $(p+1)$-colored bipartite graphs (henceforth ‘graphs’) with spins $S^a_i$ on the external legs. Denoting as $k$ the order of the effective coupling between replicas $a_1 \cdots a_k$, this can be pictured as

$$-\beta H_{\text{eff}}(\{S^a\}) = \sum_k \beta^k \sum_{a_1 \cdots a_k} a_1 \cdots a_k G_k$$

(15)

Here the solid line is the $J$-propagator (tensor lines with color 0), and the $p$ dashed line emerging from each external leg represents the external spin variables $S^a_i$. The blob $G_k$ is the large $N$ tensor connected $k$-point function, i.e. the sum over all connected melonic graphs with $k$ external (solid) legs. For each graph contributing to the blob amplitude, the site indices $i_j$ of the spins are contracted along ‘broken faces’, i.e. connected paths with alternating color $1 \leq c \leq p$ and 0, from one external dashed leg to another, through the graph.

Let us now show that the $k = 2$ term dominates in the large $N$ limit. Observe that powers of $N$ in $H_{\text{eff}}(\{S^a\})$ have three sources: the tensor propagators, the bubble interactions $\text{tr}_B(J,J)$, and the sums over site indices $i$. The first two contributions are those of a melonic graph with $k$ cut lines of color 0 whose scaling has been found in the appendix of [7] to be $p - (p-1)k - \rho$, where $\rho$ is a positive number independent of $k$. As for the spin contribution, from (4) we see that it gives at most a factor of $N$ per broken face, and there are at most $pk/2$ of them. This gives for the scaling degree $\omega(k)$ in $N$ of the order-$k$ term of (15)

$$\omega(k) \leq p - \left(\frac{p}{2} - 1\right) k.$$

(16)
We conclude that it is indeed the case that only \( k = 2 \) terms are relevant in the large \( N \) limit. Thus, at leading order (15) reduces to

\[
- \beta H_{\text{eff}}(\{S^a\}) = \beta^2 \sum_{a,b} G_2 \begin{array}{cc}
\vdots & \vdots \\
a & b \\
\end{array}
\]

\( (17) \)

To complete our evaluation of the effective Hamiltonian, we must compute the two-point function \( (G_2)_{i_1...i_p; j_1...j_p} = [J_{i_1...i_p} J_{j_1...j_p}] \) of the tensor. Its scaling with \( N \) is \( N^{-(p-1)} \).

Its tensorial structure is \( \prod_{l=1}^p \delta_{i_l,j_l} \) which identifies, by pairs, the lattice sites between the replicas \( a \) and \( b \). Finally its amplitude, simply denoted as \( G_2 \), is found by inserting the universality property (11) into the Schwinger–Dyson equation (12), yielding

\[
\frac{G_2}{\sigma^2} + \sum_{m \geq 2} \left( \sum_{B \in B_m} t_B \right) m G_2^m = 1,
\]

\( (18) \)

in which \( B_m \) denotes the set of melonic bubbles with \( 2m \) vertices. The leading-order connected two-point function is the solution of this polynomial\(^6\) equation, and depends on the whole set of coupling constants \( t_B \). For example, for a potential with a single four-vertex bubble (see figure 1) with coupling constant \( t \), equation (18) becomes

\[
2\sigma^2 t G_2(t) + G_2(t) = \sigma^2,
\]

\( (19) \)

and hence, picking the solution with \( G_2(0) = \sigma^2 \),

\[
G_2(t) = \frac{\sqrt{1 + 8\sigma^4 t} - 1}{4\sigma^2 t}.
\]

\( (20) \)

This is a smoothly decreasing function of \( t \geq -1/8\sigma^4 \).

Summarizing, we have proved that

\[
- \beta H_{\text{eff}}(\{S^a\}) = \frac{\beta^2 G_2}{N^{p-1}} \sum_{a,b} \sum_{i_1...i_p} \prod_{l=1}^p S_i^a S_i^b,
\]

\( (21) \)

which is the usual \( p \)-spin replica Hamiltonian [11, 16], except for the variance \( \sigma^2 \) which is replaced by \( G_2 \) (which as we saw can be computed exactly for a given tensor quenched potential \( V \)). This is the content of our universality theorem, the main result of this work. It shows that the higher order terms in the quenched distribution change the critical temperature, but not the structure of the low temperature phase.

2. Conclusion and outlook

We have introduced large random tensors as a new tool for spin glass theory. Using the peculiar scaling behavior of tensors in the \( p \)-unitary ensemble, we have identified an infinite universality class of infinite-range \( p \)-spin glasses with non-Gaussian correlated quenched distributions. To our knowledge, this is the first universality theorem of spin glass theory with this level of generality.

We close with a more prospective remark. Just like their Sherrington–Kirkpatrick relatives, the \( p \)-spin interactions in (3) have infinite range, and for this reason \( p \)-spin glass

\^6 Or analytic, if \( V \) has infinitely many bubble terms.

models are judged (at least partially) unphysical. We expect however that random tensor techniques should be applicable to finite-range models too. Indeed, from the random tensor perspective, a finite-range spin glass model is one for which the $J$-propagator is non-trivial, and in particular depends on the tensor indices of $J$. A typical example of interest here would be

$$\sigma_{i_1 \ldots b_i, j_1 \ldots b_j}^2 = \frac{\prod_{k=1}^p \delta_{i_k, j_k}}{\sum_{1 \leq l < k \leq p} (i_l - j_k)^2 + 1},$$

(22)

which goes to zero when the lattice sites are far away. Such tensor models have already been considered in the context of quantum gravity [18], where they have been called tensor field theories (TFT). The key difference between TFT and the simple tensor models considered in this work is the appearance of a renormalization flow. The first renormalizable TFT has been identified in [19], and developments are happening quickly in this area. We expect that these new techniques will prove useful in the difficult field of finite-range spin glass theory.
