ABSTRACT

BACKGROUND AND PURPOSE: Vulnerable carotid plaque components are reported to increase the risk of cerebrovascular events. Yet, the relation between plaque composition and subclinical ischemic brain disease is not known. We studied, in the general population, the association between carotid atherosclerotic plaque characteristics and ischemic brain disease on MR imaging.

MATERIALS AND METHODS: From the population-based Rotterdam Study, 951 participants underwent both carotid MR imaging and brain MR imaging. The presence of intraplaque hemorrhage, lipid core, and calcification and measures of plaque size was assessed in both carotid arteries. The presence of plaque characteristics in relation to lacunar and cortical infarcts and white matter lesion volume was investigated and adjusted for cardiovascular risk factors. Stratified analyses were conducted to explore effect modification by sex. Additional analyses were conducted per carotid artery in relation to vascular brain disease in the ipsilateral hemisphere.

RESULTS: Carotid intraplaque hemorrhage was significantly associated with the presence of cortical infarcts (OR, 1.9; 95% confidence interval, 1.1–3.3). None of the plaque characteristics were related to the presence of lacunar infarcts. Calcification was the only characteristic that was associated with higher white matter lesion volume. There was no significant interaction by sex.

CONCLUSIONS: The presence of carotid intraplaque hemorrhage on MR imaging is independently associated with MR imaging–defined cortical infarcts, but not with lacunar infarcts. Plaque calcification, but not vulnerable plaque components, is related to white matter lesion volume.

ABBREVIATIONS: PD = proton density; WML = white matter lesion

Identification of individuals who are at high risk for cerebrovascular events is an important goal in the prevention of cerebrovascular disease. There is growing awareness that the risk of a cerebrovascular event depends on not only the severity of carotid stenosis but also the morphology and composition of the atherosclerotic plaque. Histologic studies indicate that specific “vulnerable” plaque characteristics, such as a large lipid core, thin fibrous cap, and intraplaque hemorrhage, are key elements to atherosclerotic plaque instability. Destabilization of plaque can lead to plaque rupture, with thrombus formation on the disrupted plaque surface and subsequent embolization of thrombus and/or plaque material into the distal vessels. Currently, MR imaging can accurately detect plaque components in the carotid arteries.

Ischemic vascular brain disease, manifesting as brain infarcts and white matter lesions (WMLs), is highly prevalent in the elderly, often occurs subclinically, and is associated with an increased risk of adverse neurologic events. It is, however, unknown whether atherosclerotic plaque composition also relates to these vascular brain lesions in the general population. Morphologically, brain infarcts can be divided into lacunar infarcts and cortical infarcts. Whereas lacunar infarcts are associated with local occlusive disease of deep perforating arteries, cortical infarcts are primarily caused by thromboembolism from extracranial arteries or the heart. For WMLs, cerebral small-vessel disease is considered the main contributory factor. Therefore, we...
hypothesized that vulnerable carotid plaque components as assessed on MR imaging are associated with cortical infarcts rather than with lacunar infarcts or WMLs.

In 951 individuals from the population-based Rotterdam Study,12 we studied the association of carotid atherosclerotic plaque components, intraplaque hemorrhage, and lipid core, with markers of ischemic brain disease on MR imaging.

MATERIALS AND METHODS

Study Population

The current study was embedded in the Rotterdam Study, a prospective, population-based study among middle-aged and elderly participants (>95% of white descent), aimed at investigating determinants of various diseases among middle-aged and elderly individuals (45 years of age or older).12 All participants are invited at regular time intervals, every 3–4 years, to the research center for follow-up examinations, including carotid ultrasonography.13 From October 2007 onward, participants with carotid wall thickening (maximum thickness, ≥2.5 mm on sonography) in the left, right, or both carotid arteries were invited for MR imaging of the carotid arteries. Until August 2010, 7151 participants of the Rotterdam Study cohort had undergone ultrasonography and were still alive. In 26.3% of these participants (n = 1882), carotid wall thickening was present on sonography. We excluded individuals who had MR imaging contraindications (n = 43), had dementia (n = 12), had physical immobility (n = 50), lived in nursing homes (n = 60), had moved outside the area (n = 54), or had undergone a carotid endarterectomy procedure (n = 4). Of the 1659 subjects eligible for carotid MR imaging, 1451 agreed to participate (response, 87.5%). Due to physical inabilities (eg, back pain) or claustrophobia, imaging could not be performed or completed in 85 individuals (5.9%), so, in total, 1366 participants underwent complete carotid MR imaging. The quality of all sequences in each carotid MR imaging was rated on a 5-point scale (1 = worst, 5 = best).14 Scans were included in the analyses if the image quality was scored ≥3 (n = 1289, 94.4%) in all carotid MR imaging sequences. Exclusion (n = 77) was mainly due to susceptibility artifacts from dental implants and motion artifacts.

For the current study, we selected participants with carotid MR imaging of sufficient quality who had also undergone an MR imaging examination of their brains as a part of the Rotterdam Scan Study,15 an ongoing study investigating age-related brain changes on MR imaging. Invitation to the Rotterdam Scan Study was independent of participation in the carotid MR imaging study. The objectives and design of the Rotterdam Scan Study have been described in detail elsewhere.16 Until August 2010, in total, 951 participants underwent complete MR imaging examinations of both carotid arteries and brain and were included in the current study. The median time interval between the brain and carotid MR imaging was 9 (25th–75th percentile, 2–21) months, with the brain MR imaging preceding the carotid MR imaging in 88.5% of the subjects.

The Rotterdam Study has been approved by the medical ethics committee according to the Population Study Act Rotterdam Study, executed by the Ministry of Health, Welfare and Sports of the Netherlands. Written informed consent was obtained from all participants.

Carotid MR Imaging

Imaging of the carotid arteries was performed on a 1.5T scanner (Signa HD; GE Healthcare, Milwaukuee, Wisconsin) with a bilateral phased array surface coil (Machnet, Eelde, the Netherlands). We planned the high-resolution MR imaging sequences so that the carotid plaques were imaged completely on both sides, with a previously described standardized protocol.17 First, both carotid bifurcations were identified by means of 2D time-of-flight MR angiography. Thereafter, high-resolution MR imaging sequences were planned to image the carotid bifurcations on both sides: a proton density (PD)–weighted FSE black-blood sequence; a PD-weighted FSE black-blood sequence with an increased in-plane resolution; a PD-weighted EPI sequence; a T2WI EPI sequence; a 3D–TIWI gradient-echo sequence; and, finally, a 3D phased-contrast MR angiography.17

Assessment of Plaque Composition on Carotid MR Imaging

Carotid plaques were analyzed by a single observer with >3 years’ experience in rating carotid MR imaging, as previously described.17 Analysis involved examination of both carotid arteries. The presence of atherosclerotic plaque was defined as carotid wall thickness of ≥2.0 mm, and carotid plaque was quantified by measuring maximum carotid wall thickness in the PD-weighted FSE images and by calculation of luminal stenosis with the NASCET criteria.18 In all carotid arteries with atherosclerotic plaque on MR imaging (n = 1752 carotids in 951 participants), the presence or absence of 3 different plaque components (calcification, intraplaque hemorrhage, and lipid core) was assessed with criteria described elsewhere.17 For examples of assessment of vulnerable plaque components, see Fig 1.

Brain MR Imaging

Brain MR imaging, details of which are described elsewhere,16 was performed on the same 1.5T scanner. In short, the imaging protocol included 3 high-resolution axial scans used for assessment of infarcts and white matter lesions (ie, a T1WI sequence, a PD-weighted sequence, and a FLAIR sequence).

Lacunar and cortical infarcts were rated on FLAIR, PD-weighted, and T1WI sequences by 1 of 5 trained raters according to criteria described previously.16 The presence of infarcts and location (left or right hemisphere) were recorded. WMLs and intracranial volume were segmented with a validated fully automated tissue-classification technique,19,20 and total WML volume was calculated by summing all WML voxels across the whole brain and per hemisphere. Quantification of WML volume was not possible in 41 brain scans because of susceptibility or motion artifacts. Therefore, 1670 of 1752 carotid arteries were used to study associations between carotid plaque characteristics and WML volumes. Readers who interpreted the brain MR imaging were blinded to the carotid MR imaging findings, and vice versa.

Cardiovascular Risk Factors

Cardiovascular covariates were ascertained with standard procedures as described previously.21 Risk factors used as covariates in the current study were hypertension (defined as grade 2 hypertension, diastolic blood pressure ≥90 mm Hg), hypercholesterolemia (total cholesterol >240 mg/dL), diabetes mellitus, and smoking status (current, former, or never).
higher and/or a fasting serum glucose level of 7 mmol/L or nonfasting serum glucose level of 11.1 mmol/L (defined as the use of blood glucose–lowering medication (classified as current, past, and never), diabetes mellitus susceptibility or motion artifacts.

WML volume was natural log-transformed because of skew-
ness of the untransformed measure. For the analyses with
WML volume as a dependent variable, persons with cortical
infarcts were excluded to avoid misclassification from gliosis
around the infarct area.

All analyses were adjusted for age, sex, and time interval be-
tween brain MR imaging and carotid MR imaging (model A).
Associations with WML volumes were also adjusted for intracra-

Prevalent Stroke
A history of stroke was based on the def-
inition in the World Health Organization
criteria, including a syndrome of rapidly developing symptoms, with an
apparent vascular cause, of focal or
global cerebral dysfunction lasting 24
hours or longer or leading to death. We
assessed prevalent stroke at baseline
during an interview and verified these
data with medical records.23

Statistical Analysis
We assessed the relation of carotid
plaque characteristics with ischemic vas-
cular brain disease (cortical infarcts, lac-
cunar infarcts, and WML volume) per
participant (in both hemispheres). In
addition, for infarcts, we also assessed
the relation of carotid plaque character-
istics per carotid artery (left/right) to
brain infarcts in the ipsilateral hemi-
sphere. For the participant-based analy-
sis, each carotid plaque component was scored positive if present
in 1 or both carotid arteries. For the artery-based analysis, only
brain infarcts in the hemisphere ipsilateral to the examined
carotid artery were taken into account. Associations between
carotid plaque characteristics and brain infarcts were analyzed
with logistic regression models, and the associations with
WML volume were analyzed with linear regression models.
WML volume was natural log-transformed because of skew-
ness of the untransformed measure. For the analyses with
WML volume as a dependent variable, persons with cortical
infarcts were excluded to avoid misclassification from gliosis
around the infarct area.

All analyses were adjusted for age, sex, and time interval be-
tween brain MR imaging and carotid MR imaging (model A).
Associations with WML volumes were also adjusted for intracra-

statistical methods per carotid artery (left/right) to
the relation of carotid plaque character-
istics with ischemic vas-
ular brain disease (cortical infarcts, la-
cunar infarcts, and WML volume) per
participant (in both hemispheres). In
addition, for infarcts, we also assessed
the relation of carotid plaque character-
istics per carotid artery (left/right) to
brain infarcts in the ipsilateral hemi-
sphere. For the participant-based analy-
sis, each carotid plaque component was scored positive if present
in 1 or both carotid arteries. For the artery-based analysis, only
brain infarcts in the hemisphere ipsilateral to the examined
carotid artery were taken into account. Associations between
carotid plaque characteristics and brain infarcts were analyzed
with logistic regression models, and the associations with
WML volume were analyzed with linear regression models.
WML volume was natural log-transformed because of skew-
ness of the untransformed measure. For the analyses with
WML volume as a dependent variable, persons with cortical
infarcts were excluded to avoid misclassification from gliosis
around the infarct area.

FIG1: MR imaging of the carotid artery with atherosclerotic plaque containing vulnerable plaque components. Examples of the presence of intraplaque hemorrhage and lipid core in a carotid plaque. A. Axial images of the left carotid artery of a 72-year-old subject with carotid plaque formation in the carotid bifurcation. On the T1-weighted gradient-echo image (T1w-GRE), the carotid plaque has a high signal intensity, identifying intraplaque hemorrhage (white arrow). B. Axial images of the right carotid artery of a 67-year-old subject with carotid plaque formation in the proximal internal carotid artery. There is no high signal intensity in the carotid plaque on the T1-weighted gradient-echo image. There is a region of low signal intensity in the plaque burden on both PD-weighted (PDw-EPI) and T2-weighted (T2w)-EPI images in the absence of high signal on the T1-weighted gradient-echo image, identifying the presence of a lipid core (white arrows).

Table 1: Characteristics of the study population (n = 951)*

| Characteristics                  | Values       |
|----------------------------------|--------------|
| Age (mean) (yr)                  | 71.2 ± 10.3  |
| Women (No.) (%)                  | 444 (46.7)   |
| Cardiovascular risk factors (No.) (%) | 489 (51.4)  |
| Hypertension, grade 2†           | 474 (49.8)   |
| Smoking                          | 233 (24.5)   |
| Diabetes mellitus                | 142 (14.9)   |
| Hypercholesterolemia             | 307 (32.3)   |
| Cerebrovascular disease          | 57 (6.0)     |
| History of clinical stroke       | 125 (13.1)   |
| MRI carotid characteristics      | 114 (12.0)   |
| Intraplaque hemorrhage (No.) (%) | 306 (32.2)   |
| Lipid core (No.) (%)             | 359 (37.7)   |
| Calcifications (No.) (%)         | 769 (80.9)   |
| Maximum plaque thickness (mean) [mm] | 3.6 ± 1.0    |
| Carotid stenosis of 0%–29% (No.) (%) | 766 (80.5)  |
| Carotid stenosis of 30%–49% (No.) (%) | 114 (12.0)  |
| Carotid stenosis of 50%–69% (No.) (%) | 51 (5.4)     |
| Carotid stenosis of 70%–99% (No.) (%) | 20 (2.1)     |
| MRI brain characteristics        | 125 (13.1)   |
| Cortical infarct on MRI (No.) (%) | 62 (6.5)     |
| Lacunar infarct on MRI (No.) (%) | 4.66 (2.24–12.49) |
| WML volume (median) [interquartile range] (mL) | 4.66 (2.24–12.49) |

RESULTS

Table 1 shows baseline variables for the 951 participants. Mean age was 71.2 ± 10.3 years, and 444 (46.7%) were women. Intraplaque hemorrhage was present in 306 (32.2%); lipid core, in 359 (37.7%); and calcification, in 769 (80.9%) participants. Cortical infarcts were present in 62 subjects (6.5%), and lacunar infarcts, in 125 subjects (13.1%). Median WML volume was 4.66 mL (interquartile range, 2.24–12.49). In 1752 carotid arteries with wall thickening, 57 cortical infarcts (3.3%) and 85 lacunar infarcts (4.9%) were present in the ipsilateral hemisphere.

Results of the multivariate adjusted analysis on the association between carotid plaque characteristics and cortical infarcts are presented in Table 2. The presence of intraplaque hemorrhage (OR, 1.9; 95% CI, 1.1–3.3), maximum carotid wall thickness (OR per millimeter increase, 1.3; 95% CI, 1.1–1.6), and carotid stenosis of $\geq30\%$ (OR, 1.8; 95% CI, 1.0–3.2) was all significantly associated with cortical infarcts in the subject-based multivariate analysis. When the association between intraplaque hemorrhage and cortical infarcts was adjusted for carotid stenosis, the estimate barely changed (OR, 1.7; 95% CI, 1.0–3.2; P = .059), though the association became borderline significant. When we excluded participants with a history of clinical stroke at baseline from the analyses (n = 57), the association between intraplaque hemorrhage and cortical infarcts became stronger (OR, 2.4; 95% CI, 1.2–4.6; P = .01, model B), whereas it did not change for maximum wall thickness (OR, 1.3; 95% CI, 1.0–1.6; P = .05) and became nonsignificant for $>30\%$ stenosis (OR, 1.5; 0.7–3.0; P = .29).

In the carotid-based analysis, intraplaque hemorrhage was also significantly associated with the presence of ipsilateral cortical infarcts (Table 2). Lipid core presence and plaque calcification were not associated with cortical infarcts in the subject-based analyses, though the association for the lipid core was borderline significant in the carotid-based analysis (OR, 1.6; 95% CI, 0.9–2.8; P = .08) (Table 2). After additional adjustments for carotid luminal stenosis, the association for intraplaque hemorrhage was nonsignificant (OR, 1.2; 95% CI, 0.6–2.4; P = .633).

In Table 3, the relation between carotid characteristics and lacunar infarcts on MR imaging is shown. There were no associations between any of the carotid plaque characteristics and the presence of lacunar infarcts. These results did not change after additional adjustment for carotid stenosis or exclusion of persons with clinical stroke or when performing artery-based analysis.

The association between carotid characteristics and WML volume is shown in Table 4. Subjects with calcifications had significantly larger WML volume (regression estimate, 0.21; 95% CI, 0.05–0.38). The presence of intraplaque hemorrhage was borderline significantly associated with higher WML volume (regression estimate, 0.13; 95% CI, −0.01–0.28; P = .07), but this was further attenuated when adjusting for cardiovascular risk factors (P = .145). These results did not change after additional adjustment for carotid stenosis or exclusion of those with clinical stroke. Maximum carotid wall thickness was significantly associated with higher WML volume (regression estimate, 0.08; 95% CI, 0.01–0.15; P = .032) when adjusting for carotid stenosis. This result was not present without adjustments for carotid stenosis.

In a sensitivity analysis in 311 subjects, excluding subjects with a time interval of $>1$ month between carotid and brain MR imaging, the estimates of the associations did not change (On-line Tables 1 and 2).

Stratification for sex did not show significant interaction by sex in any of the analyses (data not shown).

DISCUSSION

In a large sample of the general population of predominantly white descent, we studied, with MR imaging, the association between vulnerable carotid plaque components and ischemic vascular brain disease. We found that carotid intraplaque hemorrhage was associated with the presence of cortical infarcts, but not with lacunar infarcts. Plaque calcification and carotid wall thickness but not vulnerable plaque components were related to higher WML volume.

One of the major strengths of our study is the large sample of middle-aged and elderly subjects from the general population. Compared with small clinical studies of patients with symptomatic brain ischemia, the use of a community-dwelling population provides information on associations between carotid plaque characteristics and ischemic brain disease that are less biased by the effects of medical intervention or lifestyle modifications. Furthermore, apart from participant-based analyses, we also assessed
the relation between left/right carotid plaque and ipsilateral ischemic brain disease, enabling us to investigate vascular brain disease in the corresponding vascular territory.

A potential limitation of our study is that a lipid core is best detected with contrast-enhanced MR imaging. Although we did not administer a contrast agent in our population-based sample, the non-contrast-enhanced sequences we used showed to be insensitive for lipid core detection. Furthermore, we assessed the presence of hemorrhage and lipid core but did not measure the size of each plaque component, which may have affected our sensitivity to detect relevant associations. Another potential limitation is the time interval between brain MR imaging and carotid MR imaging, which was, on average, 9 months, with brain MR imaging preceding carotid MR imaging in 89% of participants. Thus, brain infarcts could potentially have preceded carotid MR imaging in 10% of participants. Therefore, brain infarcts could potentially have preceded carotid MR imaging. However, because the main aim of our study was not risk prediction but investigating etiologic parallels between plaque vulnerability and stroke, we believe that this sequencing will not have seriously influenced our results. Also, adjustment for time interval and sensitivity analysis in subjects with short time intervals between carotid and brain MR imaging did not change our results. Last, our cross-sectional study design makes it difficult to interpret cause and effect of the associations found.

In our study, the presence of intraplaque hemorrhage was related to cortical infarcts, and this seemed primarily true for men. A small cross-sectional study in patients with recent ischemic events and carotid stenosis found that the size of intraplaque hemorrhage and not the presence of a lipid core was associated with symptomatic plaques. On the other hand, in a prospective MR imaging study in subjects with 50%–79% carotid stenosis, both intraplaque hemorrhage and the size of the lipid core were related to the risk of a cerebral vascular event, albeit not the presence of a lipid core itself. In our study, we only found a borderline significant association between the presence of a lipid core and cortical infarcts, and only for the ipsilateral hemisphere. Thus, on the basis of our findings and those of others, it may be hypothesized that carotid intraplaque hemorrhage, rather than the presence of a lipid core, is a more relevant indicator of plaque vulnerability. However, other studies with a more sensitive measure of lipid core and assessing lipid core size should further explore the relation between lipid core and cortical infarcts.

The association we found between intraplaque hemorrhage and the presence of cortical infarcts is in line with the presumed etiology of cortical infarcts, which are primarily regarded as being caused by large-vessel disease. In contrast, lesions in subcortical brain regions, such as lacunar infarcts and white matter lesions, are considered the sequela of cerebral small-vessel disease. In our study, none of the vulnerable plaque characteristics—intraplaque hemorrhage and lipid core—were associated with the presence of lacunar infarcts, supporting this assumption.

### Table 3: Associations between subjects’ carotid plaque characteristics and WML load (*n* = 887)

| Plaque components | Per Participant (n = 951) | Per Carotid Artery (n = 1752) |
|-------------------|---------------------------|------------------------------|
|                   | Model A | P Value | Model B | P Value | Model C | P Value | Model A | P Value | Model B | P Value | Model C | P Value |

**Note:** —NA indicates not applicable.

4 Values represent increase in white matter lesion load (natural log-transformed) (95% confidence intervals) for the presence of plaque components, the presence of carotid stenosis of ≥30%, or per-millimeter increase in maximum wall thickness.

5 Model A is adjusted for age, sex, and time interval between brain MR and carotid MRI.

6 Model B is adjusted for age, sex, time interval between brain MRI and carotid MRI, and major cardiovascular risk factors (hypertension, smoking, diabetes mellitus, and hypercholesterolemia).

7 Odds ratio per millimeter increase.

8 Odds ratio of carotid stenosis of ≥30%.

### Table 4: Associations between carotid characteristics and lacunar infarcts

| Plaque components | Model A | P Value | Model B | P Value | Model C | P Value |
|-------------------|---------|---------|---------|---------|---------|---------|
| Intraplaque hemorrhage | 0.13 (−0.01–0.28) | .707 | 0.11 (−0.04–0.25) | .145 | 0.13 (−0.02–0.27) | .083 |
| Lipid core | −0.09 (−0.22–0.05) | .203 | −0.06 (−0.19–0.07) | .353 | −0.08 (−0.20–0.05) | .277 |
| Calcification | 0.23 (0.06–0.39) | .007 | 0.21 (0.05–0.38) | .010 | 0.21 (0.05–0.37) | .008 |
| Measures of plaque size | Maximum carotid wall thickness | 0.05 (−0.02–0.12) | .131 | 0.04 (−0.03–0.10) | .235 | 0.08 (0.01–0.15) | .032 |
| ≥30% stenosis | −0.10 (−0.26–0.07) | .241 | −0.11 (−0.27–0.05) | .181 | NA | NA |

**Note:** —NA indicates not applicable.

8 Regression coefficients per millimeter increase.
extracranial carotid embolic disease not being an important factor in the development of lacunar infarcts.

We did not find important differences between the participant-based analyses and the analyses restricted to the ipsilateral hemisphere of each carotid artery, though the degree of carotid stenosis was a confounder for the association between intraplaque hemorrhage and ipsilateral cortical infarcts. Previously, a relationship between plaque burden expressed as severity of stenosis and the presence of intraplaque hemorrhage has been demonstrated. Intraplaque hemorrhage instead of the severity of stenosis must be considered as the link between atherosclerotic disease and brain infarcts. The predictive power of intraplaque hemorrhage versus stenosis should be evaluated in future studies. In addition, atherosclerosis in one vessel bed is known to reflect atherosclerotic activity in other vascular regions. Thus, carotid plaques are not per se only related to ischemic disease in the ipsilateral vascular territory. If we extended this concept of atherosclerosis as a generalized disease, intraplaque hemorrhage could be regarded as a focal manifestation of an underlying systemic disease process that includes several vulnerable lesions.

In the ongoing discussion on the pathogenesis of WMLs, the most generally accepted concept is that they reflect a process of ischemic demyelination, predominantly with small-vessel disease as the etiologic factor. There is, however, also some evidence that large-vessel disease may contribute to the development of WMLs, especially via embolic events from unstable carotid plaques (ie, those with intraplaque hemorrhage). Although we found a borderline significant relation between carotid intraplaque hemorrhage and WML volume, this association attenuated when adjusting for cardiovascular risk factors. This finding may suggest that there is a shared etiology for atherosclerosis and the development of WMLs, rather than a direct causal connection between intraplaque hemorrhage and WML development.

In the current literature, all available data on this topic are from small studies in clinical patients, with 2 thoughts being put forward. Altf et al found, in 187 symptomatic subjects, an association between carotid intraplaque hemorrhage and WML volume, supporting the large-vessel disease and unstable plaque concept. Kwee et al found, in 50 patients with symptomatic carotid stenosis, that carotid plaque burden was significantly associated with WML severity but that there was no causal relationship between carotid plaque vulnerability and the occurrence of WMLs. In contrast, Patterson et al found MR imaging plaque morphology (ie, plaque size, the presence of intraplaque hemorrhage, or lipid core) in 80 carotid arteries to be not independently predictive of the severity of WMLs, refuting the large-vessel disease and unstable plaque concept. Our results suggest no significant relation between intraplaque hemorrhage or lipid component and WML volume; therefore, our results contribute to this discussion in that they do not support the hypothesis of a role of vulnerable large-vessel atherosclerotic plaque in the development of WMLs. In the current study, carotid plaque calcification is associated with WMLs, also demonstrated in a previous CT-based study by Bos et al. This is possibly the association between luminal stenosis and brain MR imaging markers of ischemia rather than vulnerable plaque, because previous studies have suggested that for a given volume of plaque, the greater the proportion of calcification, the more “stable” the plaque is.

CONCLUSIONS

The presence of carotid intraplaque hemorrhage and measures of carotid plaque size, as defined with MR imaging, are associated with MR imaging–defined cortical infarcts, but not with lacunar infarcts. Plaque instability does not seem to play a role in WML development.
