ABSTRACT: We report the preparation and application of a heterostructured photoelectrocatalyst comprising carbon nanoparticles (CNPs) and boron codoped BiVO₄ and WO₃ for the removal of an organic dye pollutant in water. The materials, synthesized by hydrothermal method, were characterized by X-ray diffraction, diffuse reflectance UV−visible spectroscopy, energy-dispersive X-ray spectroscopy, and electron microscopy. The catalysts were immobilized on treated titanium sheets by drop-casting. The fabricated electrodes were characterized by linear sweep voltammetry (LSV) and chronoamperometry. Diffuse reflectance spectroscopy of the catalysts reveals that the incorporation of CNPs and B into the structure of monoclinic BiVO₄ enhanced its optical absorption in both UV and visible regions. The LSV measurements carried out in 0.1 M Na₂SO₄ showed that the BiVO₄- and WO₃-based photoelectrode demonstrated significant photoactivity. CNP/B-BiVO₄ and CNP/B-BiVO₄/WO₃ photoanodes gave photocurrent densities of approximately 0.83 and 1.79 mA/cm², respectively, at 1.2 V (vs 3 M Ag/AgCl). The performance of the electrodes toward degradation of orange II dye was in the order BiVO₄ < B-BiVO₄ < WO₃ < CNP-BiVO₄ < CNP/B-BiVO₄ < CNP/B-BiVO₄/WO₃, and the apparent rate constants obtained by fitting the experimental data into the Langmuir Hinshelwood kinetic model are 0.0924, 0.1812, 0.254, and 0.845 h⁻¹ for BiVO₄, WO₃, CNP/B-BiVO₄, and CNP/B-BiVO₄/WO₃, respectively. The chemical oxygen demand abatement after 3 h of electrolysis at the best performing photoanode was 58%. The study showed that BiVO₄ and WO₃ are promising anodic materials for photoelectrocatalytic water treatment plant.

1. INTRODUCTION

Photoelectrocatalytic (PEC) process has been indicated to hold promise for wastewater remediation and energy conversion. In this technique, electrical energy is applied to a photocatalytic system to obtain synergistic benefit. In the last few years, combining electrochemical process and photocatalysis has been shown to yield improved performance for organic pollutant degradation compared to either electro-oxidation or photocatalysis alone. This enhanced performance has been attributed to the ability of the applied bias potential to promote the separation of the photogenerated hole and electron pairs.

Photocatalysts that are sensitive in the visible region of the solar spectrum have received considerable attention as anodic materials for PEC because utilizing sunlight for the process promotes sustainability. For instance, BiVO₄ and its composites have been used as photoanodes in the PEC system for hydrogen production via water splitting and organic contaminant decomposition. Having a narrow band gap of 2.4 eV, BiVO₄ is an ideal semiconductor for visible-light-driven processes. It is nontoxic, stable to photocorrosion, inexpensive, and can be obtained via simple synthetic routes. However, apart from the rapid recombination of electron−hole pairs, BiVO₄ also suffers from poor electrical conductivity and low adsorptive performance. These drawbacks make BiVO₄ an inefficient photocatalyst for pollutant degradation.

Studies have shown that the photocatalytic/PEC degradation of organic pollutants at pristine BiVO₄ presented low removal efficiency. WO₃ (band gap, 2.5−2.8 eV) is another promising material for PEC. It is inexpensive, demonstrates low susceptibility to photocorrosion, exhibits appreciable stability in acidic and oxidative conditions, and nontoxic. Importantly, WO₃ is being explored as a potential photocatalyst for destruction of organic pollutants because of the high oxidation power of its valence-bound holes. In spite of its impressive properties, the photocatalytic activity of WO₃ is poor owing to its relatively low conduction band edge. The position of the conduction band edge is unfavorable for one-electron reduction of adsorbed oxygen molecules. This leads to accumulation of photogenerated electrons and their consequent recombination with the holes which are needed for oxidation of target compounds. As a result, improving the photocatalytic activity of WO₃ by modifying its electronic structure has been the focus of many studies. It has been reported that tuning the morphology/structure of WO₃ can yield a catalyst with enhanced charge separation and improved photoactivity. Theerthagiri et al., Zhang et al., and Yao et al., in separate studies, showed that WO₃ nanoparticles possess suitable physicochemical properties for enhanced photocatalytic performance.

Fabricating a hybrid of two or more semiconductors has been hinted as one of the plausible approaches to overcome the challenges of electron and hole recombination. Similarly, some other limitations associated with individual photocatalyst such as the low conduction band edge in WO₃ and the poor charge mobility in BiVO₄ can also be circumvented by this approach. The resulting nanocomposite catalysts have been reported to display much higher activity than the individual materials. Xia et al. reported the oxidation of phenoxy on a Fe₂O₃/BiVO₄ thin film anode via PEC process. The composite photoanode demonstrated superior performance to the pristine BiVO₄ anode. The authors attributed the enhanced degradation performance to the ultrathin iron oxide, which minimized charge carrier recombination in BiVO₄. In another report by Martins et al., WO₃-modified TiO₂ nanotube array (NTA) exhibited better mineralization efficiency than the unmodified TiO₂ (NTAs) when both electrodes were employed for the PEC degradation of the endocrine-disrupting compound propyl paraben. Similarly, Wei et al. reported that decontamination of coking wastewater containing phenolic compounds was much more efficient at heterostructured TiO₂/g-C₃N₄ than at pure TiO₂ and g-C₃N₄. The improvement in the PEC efficiency was attributed partly to the heterojunction that is formed between the two photocatalysts which suppresses the recombination rate of electrons and holes. In this work, BiVO₄ has been modified with carbon nanoparticles (CNPs) and boron to obtain a photocatalyst denoted as CNP/B-BiVO₄. This catalyst was then coupled to WO₃ nanorods and the resulting nanocomposite was immobilized on Ti plate. The photoanode, CNP/B-BiVO₄/WO₃ was then employed for the catalytic oxidation of orange II dye. A few studies have reported the use of BiVO₄/WO₃ as anodic material in PEC experiments. In this study, we hypothesized that modification of BiVO₄ with substances such as CNP and B would impact positively on the photocatalytic performance of the semiconductor. In addition, we envisaged that coupling this modified material to WO₃ nanorods will provide a nanocomposite anode with desirable properties for PEC applications.

2. RESULTS AND DISCUSSION

2.1. XRD Analyses. The X-ray diffraction (XRD) patterns of the electrode materials are shown in Figure 1. The diffraction peaks in the XRD pattern of pure BiVO₄ (Figure 1) can be indexed to monoclinic scheelite structure of BiVO₄ (JCPDS card no. 14-0688). The XRD pattern of CNPs and B codoped BiVO₄ shows an additional peak at 24°, which can be ascribed to the (002) plane of graphite. The XRD pattern of WO₃ (Figure 1b) shows diffraction peaks at 2θ = 14.1, 22.9, 28.2, 36.5, 49.9, and 55.4°, which correspond to the (100), (001), (200), (201), (220), and (221) crystal planes, respectively, of the hexagonal structure of WO₃ (JCPDS card no. 75-2187).

2.2. Morphology Investigations, EDS Analysis, and Elemental Mapping. The scanning electron microscopy (SEM) and transmission electron microscopy (TEM) images, energy-dispersive spectroscopy (EDS) spectra, and elemental maps are presented in Figures 2 and 3. From the SEM image of pristine BiVO₄ (Figure 2a), it can be observed that the sizes of the nanoparticles formed are largely uniform. The particles seem to be closely packed. The SEM image of the doped BiVO₄ (Figure 2b) shows a morphological characteristic of a composite material. It shows some plate-like structures with embedded particles and the constituents seem to be well integrated. The electron images show that the dimensions of the materials are much less than 100 nm. The elemental map (Figure 2c) confirms the presence of B in the nanocomposite, with the element uniformly distributed within the material.
Similarly, Figure 2d reveals that carbon particles are present in the nanocomposite material. The EDS spectrum (Figure 2e) further confirms the presence of B, although it has a very low intensity owing to its very low concentration compared with the other elements in the composite material.

The TEM images of the synthesized WO₃ nanorods are shown in Figure 3a,b. The image at 1 μm (Figure 3a) reveals that the rods are of different lengths, but the diameter seems to be essentially the same. The TEM image of the carbon particles is presented in Figure 3c, where the particles appear to be spherical and agglomerated.

2.3. BET Surface Area Analysis. Nitrogen adsorption–desorption experiment was performed to investigate the Brunauer–Emmett–Teller (BET) surface area of the pristine and composite materials. The adsorption isotherms of BiVO₄, CNP, CNP/B-BiVO₄, and WO₃ are shown in Figure 4, and the specific BET surface area are presented in Table 1. From the values in the table, it is obvious that incorporation of CNP into the lattices of BiVO₄ resulted in an increase in the surface area of the photocatalyst. Higher surface area is beneficial for interaction between the organic pollutant and the photoelectrocatalyst, and this will aid overall degradation efficiency. Similarly, the comparatively high BET surface area of WO₃ nanorods will contribute significantly to the adsorption capability of the heterojunction photoanode, which will enhance its catalytic performance.

2.4. Diffuse Reflectance Spectroscopy. Diffuse reflectance spectroscopy (DRS) is a valuable technique that can be used to gain insights into the electronic states of semiconducting materials. The UV–vis absorption spectra of BiVO₄, WO₃, and CNP/B-BiVO₄ are shown in Figure 5. The intrinsic absorption bands of both the pristine BiVO₄ and doped BiVO₄ span over the UV and visible light regions, while that of WO₃ seem to be strong within the UV region, extending slightly into the visible region. This absorption characteristic of WO₃ is in agreement with earlier reports. The doped BiVO₄ demonstrates superior visible light absorption compared to the pristine BiVO₄. In addition, the absorption edge of the CNP and B codoped BiVO₄ exhibits a red shift. The extension of the absorption edge of the doped material may be as a result of band transitions occurring because of the presence of impurities in the forbidden band.

The band gap energies of the catalysts (Figure 6) were estimated from a plot of $F(R) \times h\nu_{\text{ref}}$ against $h\nu$, where $F(R)$ is the Kubelka–Munk function given by $(1 - R)^2 / 2R$, and $h\nu$ is the incident photon energy.

2.5. Linear Sweep Voltammetry and Photocurrent Response. The linear sweep voltammograms of the fabricated photoanodes were obtained in the dark and in the presence of light. As shown in Figure 7a, the current responses of both CNP/B-BiVO₄ and CNP/B-BiVO₄/WO₃ in the dark are not significantly different until reaching a potential of about 1.0 V, with the CNP/B-BiVO₄/WO₃ electrode displaying a slightly higher current than the codoped BiVO₄ electrode (0.16 and 0.15 mA/cm² at 1.3 V). Apparently, the presence of WO₃ contributed to the current signal of the CNP/B-BiVO₄/WO₃ electrode. It is well known that WO₃ exhibits better charge-transfer property than BiVO₄. In addition, in both doped BiVO₄ and heterostructured electrodes, photocurrent seems to increase as the anodic potential increases. In the presence of light, the photoanodes showed markedly higher photocurrents (1.25 and 2.20 mA/cm² at 1.3 V for CNP/B-BiVO₄ and CNP/B-BiVO₄/WO₃, respectively) than those recorded under dark condition (Figure 6b). The significant photocurrent enhancement recorded by the coupled semiconductor anode can be attributed to the contributions from both BiVO₄ and WO₃ (Figure 7b). The excellent charge transport property of WO₃ and the high visible light activity of BiVO₄ are beneficial for improved photoactivity. As evident in Figure 7b, the photocurrent responses at both CNP/B-BiVO₄ and CNP/B-BiVO₄/WO₃ are stable over the time range shown.

2.6. PEC Degradation Experiments. Degradation of orange II sodium salt was carried out at the fabricated electrodes to evaluate their PEC performance. The oxidation process was performed at an applied anodic potential of 2.0 V. The removal efficiency of the dye was calculated from the following relation:

\[
\text{% removal} = \left( A_0 - A_t \right) / A_0 \times 100
\]

where \(A_0\) and \(A_t\) are the absorbance values at time \(t = 0\) and \(t = t\), respectively.

As can be seen in Figure 8a, the CNP/B-BiVO\(_4\)/WO\(_3\) electrode exhibited the highest degradation efficiency with 92% removal of the dye in 3 h of the PEC process. The performance of the photoanodes follows the order BiVO\(_4\) < B-BiVO\(_4\) < WO\(_3\) < CNP/B-BiVO\(_4\) < CNP/B-BiVO\(_4\)/WO\(_3\). Degradation efficiency at B-doped BiVO\(_4\) photoanode is only slightly higher than that obtained at the pristine BiVO\(_4\) anode (data not shown). Wang et al. made similar observation in the photocatalytic performance of BiVO\(_4\) and B-BiVO\(_4\)\(^{53}\). The authors reported that boron doping narrows the band gap energy of the photocatalyst by a magnitude of 0.04 eV, thus increasing its light absorption in the visible region. It was also suggested that interstitial boron doping can increase the number of oxygen vacancies and V\(^{4+}\), leading to red shifting of the absorption edge and consequently improved photocatalytic performance in the visible light region. It is noteworthy that the performance of pristine BiVO\(_4\) is inferior to that of the pure WO\(_3\) nanorods despite the former being a better absorber of visible light. The poor conductivity and low adsorption capability of BiVO\(_4\) are some of the factors responsible for its low PEC performance. On the other hand, the relatively large surface area of WO\(_3\) and its excellent conductivity are favorable for the degradation of organic pollutants. However, incorporation of CNP into BiVO\(_4\) leads to significant improvement in its PEC performance. In essence, the CNP and B codoped BiVO\(_4\) showed much more enhanced performance. Also, incorporation of CNP into the structure of BiVO\(_4\) could lead to improved charge transport property and enhanced adsorption capability of the photocatalyst. Apparently, the CNP/B-BiVO\(_4\)/WO\(_3\) performed best because of the contributions of the various

| sample          | BET surface area/m\(^2\) g\(^{-1}\) |
|-----------------|-------------------------------------|
| BiVO\(_4\)      | 1.81                                |
| CNP            | 84.32                               |
| CNP/B-BiVO\(_4\) | 2.49                                |
| WO\(_3\)       | 36.26                               |

Table 1. BET Surface Area of Pristine BiVO\(_4\), CNP, Doped BiVO\(_4\), and WO\(_3\)
constituent materials. The kinetic rate constants obtained by fitting the degradation experimental data into the Langmuir Hinshelwood kinetic model are 0.0924, 0.1812, 0.254, and 0.845 h$^{-1}$ for BiVO$_4$, WO$_3$, CNP/B-BiVO$_4$, and CNP/B-BiVO$_4$/WO$_3$, respectively. Figure 8b displays the plots of normalized concentration abatement of the dye via photolysis, electrolysis, and photoelectrocatalysis. It can be seen that the coupled process offers a far more efficient removal of the dye.
than the individual processes. This observation further affirms the superiority of PEC oxidation process to both electrochemical oxidation and photocatalytic oxidation processes. The chemical oxygen demand (COD) decay after 3 h of the PEC process at the preferred anode was 58%. For possible practical application, the photoelectrocatalyst (CNP/B-BiVO4/WO3) was further employed for the degradation of 50 mg L−1 (50 mL) of the dye solution under the same experimental conditions. A 56% decolourization was obtained after 3 h of the process.

3. CONCLUSIONS

Two visible-light-sensitive semiconductors, namely, BiVO4 and WO3, have been synthesized, characterized, and applied for the degradation of a model organic pollutant, orange II dye. BiVO4 was modified with CNP and B to improve its charge transport property and adsorption behavior to increase its PEC efficiency. The kinetic rate constants calculated for the degradation of the contaminants at BiVO4 and WO3 photoanodes were 0.0924 and 0.1812 h−1, respectively. The much better performance of WO3 nanorods compared to the undoped BiVO4 may not be unrelated to its morphology, which can retard recombination of photogenerated electron–hole pairs. Doping CNP and B into the structure of BiVO4 led to significant improvement in its PEC performance. Coupling the doped BiVO4 to WO3 yielded a heterostructured anodic material which showed much more excellent properties than the individual components. The higher performance of this electrode can be linked to the formation of n–n heterojunction, which promotes separation of charges and generation of a large amount of the valence-bound holes, which are needed for the oxidation of the pollutant. This study shows that BiVO4- and WO3-based anodes have prospects for water remediation via photoelectrocatalysis.

4. EXPERIMENTAL SECTION

4.1. Materials. Sodium tungstate dihydrate (Na2WO4·2H2O), bismuth nitrate pentahydrate (Bi(NO3)3·5H2O), sodium metavanadate (NaVO3), sodium chloride (NaCl), sodium sulfate (Na2SO4), sodium hydrogen carbonate (NaHCO3), sodium hydroxide (NaOH), and ethanol were purchased from Sigma-Aldrich, South Africa. All materials were prepared with deionized water. Ethanol was purchased from Sigma-Aldrich, South Africa. All solutions were prepared with deionized water.

4.2. Synthesis of WO3 Nanorods. The synthesis of WO3 nanorods is as follows: 2.62 g of Na2WO4·2H2O was dissolved in 80 mL of deionized water. The material was then dried at 80 °C for 24 h. After cooling to room temperature, the synthesized material was transferred into a Teflon-lined autoclave, sealed, and put into the stainless steel shell. This was then maintained 180 °C for 24 h in an oven. Upon cooling, the material was transferred into centrifuge tubes and washed a few times with water. The yellow substance obtained after decantation was dried in an air oven at 80 °C for 8 h. Preparation of CNP/B-BiVO4 followed the same procedure except that 1.0 g of H3BO3 and 10 mg of CNP were added to the solution of NaVO3 prior to mixing with Bi(NO3)3·5H2O solution.

4.3. Preparation of CNPs, BiVO4- and CNP/B-BiVO4. CNPs were prepared from oats purchased from a local market in Johannesburg, South Africa. Oats (5 g) was powdered by grinding. The powder was then put into a crucible and transferred into a muffle furnace maintained at 400 °C for 2 h. The black material formed was allowed to cool to room temperature, pulverized, and subsequently dispersed in deionized water. The dispersion was centrifuged and the supernatant was decanted into a clean beaker. This process was repeated several times to obtain more supernatants. The water in the supernatant was evaporated and the solid particles left in the beaker were collected and kept for use.

To synthesize pristine BiVO4, 0.61 g of NaVO3 was dissolved in about 40 mL of deionized water and 2.43 g of Bi(NO3)3·5H2O were dissolved in 0.1 M HNO3. The NaVO3 solution was then gradually added to the Bi(NO3)3 solution. The yellow precursor solution formed was transferred into a Teflon-lined autoclave, sealed, and put into the stainless steel shell. This was then maintained 180 °C for 24 h in an oven. Upon cooling, the material was transferred into centrifuge tubes and washed a few times with water. The yellow substance obtained after decantation was dried in an air oven at 80 °C for 8 h. Preparation of CNP/B-BiVO4 followed the same procedure except that 1.0 g of H3BO3 and 10 mg of CNP were added to the solution of NaVO3 prior to mixing with Bi(NO3)3·5H2O solution.

4.4. Characterization of the Materials. Powder XRD analysis of the catalysts was done on a Rigaku Smartlab X-ray diffractometer (USA) equipped with Cu kα radiation and operated at 40 kV and 40 mA. The electron images were obtained on a scanning electron microscope (TESCAN, VEGA3 XMU, Czech Republic) and transmission electron microscope (JEOL 2100 HRTEM 200V, Japan). Energy-dispersive X-ray spectrometry analysis was performed on the equipment attached to the scanning electron microscope. DRS was done on a UV–visible spectrophotometer (Shimadzu 2450, Japan), and concentration abatement of the dye was monitored on a UV–visible spectrophotometer (Agilent Cary 60, Malaysia) at its wavelength of maximum absorption. COD was determined on a HACH DR3900 spectrophotometer.

4.5. Fabrication of Electrodes. Ti sheets were first degreased in 40% m/m NaOH solution heated to 80 °C and maintained for 2 h. Etching of the sheets was then carried out in a 18% v/v HCl solution maintained at 98% for 2 h. The dispersions of BiVO4- and CNP/B-BiVO4 were prepared by weighing 0.2 g of each of the catalysts into an ethanolic solution of PEG (containing 2 mL of ethanol and 1 mL of PEG). A mixture of both CNP/B-BiVO4 and WO3 was also prepared by dispersing 0.1 g of each of the catalysts in an ethanolic solution of PEG. The dispersions were ultrasonicated for 60 min.

The dispersion (100 μL) was drop-cast onto both sides of the prepared Ti sheets with an exposed area of 4 cm2. The coated sheets were dried in an air oven at a temperature of 250 °C. The coating was repeated once more and the sheets were sintered at 500 °C in a muffle furnace.

4.6. Electrochemical Experiments. Electrochemical measurements were done on a computer-controlled potentiostat (Autolab PGSTAT 302N) using a three-electrode system. The working electrodes used included BiVO4/Ti, B-BiVO4/Ti, CNP–BiVO4/Ti, CNP/B-BiVO4/Ti, WO3/Ti, and CNP/B-BiVO4/WO3/Ti. The reference electrode was Ag/AgCl (3 M KCl), and the counter electrode was a coiled platinum wire. Linear sweep voltammetric measurements were carried out in a 0.1 M solution of Na2SO4 and amperometric measurements in the presence and absence of photons were performed in 5 mg L−1 solution of orange II sodium salt (prepared in 0.1 M NaCl).
Na₂SO₄). Electrochemical oxidation of the dye was carried out in a quartz photoelectrochemical cell in the presence and absence of light. Typically, 250 mL of the simulated wastewater (containing 5 mg L⁻¹ of the analyte) was electrolyzed in an experiment with continuous stirring of the electrolytic solution. The solar light source was an Oriel solar simulator. The simulator has a xenon lamp of 100 W and a UV cutoff filter (Air Mass 1.5 Global filter), giving 1.0 sun output. The distance between the photoelectrochemical cell and the light source was about 5 cm.
