(Dated: October 15, 2008)

We performed scanning tunneling spectroscopic experiments on hole-doped NdBa$_2$Cu$_3$O$_{7-δ}$. The $dI/dV$ curves obtained at 4.2 K are asymmetric with clear peak-dip and hump structures. Energy derivatives of these curves show peaks at energies beyond the dip features. Highly precise full potential bandstructure calculations confirm a featureless electronic density of states in that energy region. Our results indicate that tunneling electrons couple to a collective mode in the CuO$_2$ plane.

The identification of the microscopic mechanism for pair formation in the unconventional superconductors is still a challenge. In conventional superconductors, apart from the isotope effect, tunneling experiments provided the most direct evidence of electron-phonon interaction mediating the Cooper-pair formation [1,2]. In case of high-$T_c$ superconductors (HTSC), inelastic neutron scattering (INS) experiments and high resolution angle-resolved photo emission (ARPES) experiments were useful to find collective modes in the range of 30-70 meV [3,4,5,6,7,8,9]. Collective spin excitations have been used to find collective modes in the range of 30-70 meV [3,4,5,6,7,8,9]. Collective spin excitations have been suggested as the bosonic mode which interacts with the electronic density of states in the CuO$_2$ plane, from scanning tunneling spectroscopy (STS) data obtained on a twinned single crystal of NdBa$_2$Cu$_3$O$_{7-δ}$ (Nd-123). Nd-123 belongs to the Y-123 family. They have isostructural unit cells. The atomic size of Nd$^{3+}$ ions, which are paramagnetic at 4.2 K [18], is bigger than that of Y$^{3+}$.

The single crystal used for the measurements was grown from a BaO/CuO flux. The details of the growth process are according to those mentioned in Ref. [18]. After the growth, the crystal was properly oxidized to achieve a $T_c$ onset of 93.5 K. The transition width of $\Delta T_c \sim 3.5$ K was determined from ac-susceptibility measurements. For the STS experiments, the as-grown crystal was cleaved with absolute ethanol and dried by pure helium gas. No special surface preparation was performed [13]. The STS measurements were carried out at 4.2 K in He gas atmosphere using a home-made STM. A mechanically cut Pt-Ir tip was used for the measurements. The tunneling parameters for the measurements were set as -0.1 V and 0.2 nA giving a tunneling resistance of 500 MΩ. The bias voltage was applied to the sample so that a negative (positive) voltage refers to a filled (empty) sample energy state. Spectroscopic data were obtained as $|dI/dV|(V)$ curves using the standard lock-in technique where a modulation voltage of 2 mV

*Electronic address: Pintu.Das@cpfs.mpg.de
(rms) was used. Data were taken at many different locations on flat areas of the sample surface. The spectra show that the surface is electronically inhomogeneous. However, at some locations of the sample, we obtained curves which are nearly homogeneous in the length scale of 20-25 nm. Here we discuss only those spectra which are nearly homogeneous in the length scale of 20-25 nm. These spectra were observed while taking a dI/dV curve at every 0.5 nm of a 32 × 32 nm² area. It is remarkable that the PDH features are observed on the as-grown sample surface. On the as-prepared surface of NdBCO, Ting et al. found the CuO chain layer as the surface terminating layer [23]. The spectra shown in Fig. 1 do not have any similarity to the ones observed on the well characterized CuO chain layer [24]. It is possible that the topmost CuO chain layer in the present case is an insulating layer due to surface degradation. In that case, at the small bias voltage range of ±100 mV, the tunneling would take place between the metal tip and the CuO₂ plane layer, which is situated within ~ 4.2 Å of the CuO chain layer, thus revealing the clear PDH features. Apart from the PDH features, the asymmetry of the coherence peaks is evident from the data. The peak height is found to be always larger at the filled sample states compared to the empty ones. Similar asymmetric curves were also observed for Bi-2212 [11, 12, 25] and Nd-123 [26] earlier. The asymmetry is most likely related to the probability of electron extraction and injection from/to the material [27]. Beyond the peaks, there is an asymmetric V-shaped background on top of which humps are evident both at empty and filled states. The humps are observed at ~ 2Δ and there are dips at ~ 1.4Δ. The respective features are broader for the empty states than for the filled ones. This becomes clear from the representative curve shown in Fig. 2. The average energy gap measured from peak to peak is 70 meV which leads to 2Δ/k_BT_c = 8.68.

Recently, Ngai et al. reported subgap features in addition to the coherence peaks in the dI/dV curves obtained on Y_{1−x}Ca_xBa_2Cu_3O_{7−δ} thin films [10]. Similar features were also reported earlier on Y-123 single crystals [15]. On the other hand, subgap features were not observed in the ARPES data on cleaved single crystal and STS data on thin film of Y-123 [28, 29]. However, the PDH features are very clearly present in those data. The subgap features were also not observed by Wu et al. on Nd-123 [26]. In cuprate systems with an additional copper-oxygen chain layer, the subgap features were suggested to be due to multiband superconductivity [10]. In our data, we do not find any indication of such an influence of the metallic chain layer on the electronic structure representing superconducting state (see Fig. 1). Interestingly, Derro et al. observed strong subgap resonances in the energy scale of ~ 5 meV while tunneling to the chain layer of Y-123 single crystals [24]. These subgap features were suggested to be possibly due to the oxygen vacancies in the chains. It is most likely that the metallic CuO chain layers acquire superconductivity due to the proximity effect [24, 30]. Within this scenario, the spectra with subgap features possibly reflect the LDOS of CuO chains and those with clear PDH features reflect...
the LDOS of CuO$_2$ plane layers as these features are also observed on chain-less Bi-2212. If the superconductivity in 123 systems would be due to multiband effects, the signature of this should also be seen in the electronic spectra of Nd-123. Although from the present data it is not clear if the subgap states would be observed in the LDOS of CuO$_2$ plane that exists in the bulk, however, it gives another indication that the PDH features are the generic features in the CuO$_2$ plane-derived DOS of cuprate superconductors.

In order to gain further information from the spectra, we focus on the part of the curves beyond the coherence peaks. By numerically differentiating the curves we observe a peak in the empty state at an energy $E_{\text{res}}$ as shown in Fig. 4. The above mentioned peaks in the $d^2I/dV^2$ curves correspond to very weak step-like features in the $dI/dV$ curves. The observed fine structure is consistent with the predicted inelastic electron tunnel spectroscopic (IETS) features in $d$-wave cuprates [13, 31]. It also has considerable similarity to the IETS features observed for hole-doped Bi-2212 [14] and electron-doped PLCCO superconductors [17]. In order to check if the fine structure in the STS spectra is due to the specific bandstructure of the superconductor, full potential density functional calculations were performed. We applied the full potential local-orbital minimal basis scheme FPLO [32] (version 5.00-19) within the local spin density approximation (LSDA), where the exchange correlation potential of Perdew-Wang [33] was chosen for the calculations. The strong Coulomb repulsion in the localized Nd 4f shell has been modeled in a mean-field way within the LSDA+U approximation. A typical value of $U_{4f} = 8$ eV has been applied throughout the calculations. Our results are basically independent of the choice of $U$ within physically reasonable limits. As basis set, Nd 4f5s5p/6s6p6d, Ba 5s5p/6s6p6d, Cu 3s3p/4s4p3d + 4d and O 2s2p3d + 3s states (notation: semicore/valence+polarization states) have been chosen. The extent of the valence states is optimized with respect to the total energy [34]. The inclusion of the semicore states is necessary to account for their nonnegligible overlap. The polarization states provide a more complete basis set to insure highly accurate bandstructure and DOS results. A very fine $k$-mesh of 16200 points in the Brillouin zone (2560 in the irreducible wedge) was used to resolve the singularities in the DOS near the Fermi level accurately. Convergence with respect to basis set and $k$-mesh was carefully checked. The structural data of Ref. [35] were used.

We find a total valence band width of about 9 eV, typical for the quasi-two-dimensional cuprates. Three bands cross the Fermi level, two of them originating from the CuO$_2$ layer and one originating from the CuO$_3$ chains along the $y$ direction. In Fig. 5 we show the calculated total DOS of Nd-123 in the vicinity of the Fermi level. In this energy region, only the states originating from the CuO$_2$ planes and the CuO$_3$ chains exhibit significant contributions. Whereas the CuO$_2$-planes-related DOS is almost constant close to the Fermi level, two distinct van Hove singularities related to the CuO$_3$ chain show up at about 85 and 110 meV. Otherwise, no significant features in the DOS near the Fermi level are obtained. The slight underdoping of the present sample can be modeled by a small rigid shift of the Fermi level towards negative energies. For an oxygen deficiency $\delta = 0.01$, this shift is estimated to be $\sim -18$ meV. There is no sharp structure present in the DOS of the CuO$_2$ plane at energies close to the region where peaks are observed in the experimental $d^2I/dV^2$ spectra. Thus, these features cannot be related to the DOS. The calculations also show that the bilayer splitting is not responsible for the PDH features.

In accordance with Eliashberg’s classical theory for strong coupling superconductors, where the electron-boson interaction was proposed to be observed at an energy of $E = \Delta + \Omega$ [36], the $\Omega$ values were determined for both empty and filled state. The empty and filled state $\Omega$ are experimentally determined by $\Omega(r) = E_{\text{res}}(r) - \Delta(r)$ from the entire set of curves obtained at different locations ($r$) on the sample. The mean values of $\Omega(r)$ are found to be $22.9 \pm 1.8$ meV and $23.7 \pm 1.6$ meV for empty and filled states, respectively. Thus, the peaks at $E_{\text{res}}$ in the $d^2I/dV^2$ curves are found to be almost symmetric. This strongly supports the assumption that the observed features are signatures of inelastic tunneling. They result from an additional tunneling channel introduced due to the excitation of a collective mode at $\sim 23$ meV. The mode energy is surprisingly low compared with the ones observed for Y-123 for similar dopings [4]. A priori, it is not clear if the mode is excited in the tunneling barrier or in the CuO$_2$ plane of the sample.
it is instructive to plot $\Omega(r)$ against $2\Delta(r)$. As shown in Fig. 2, $\Omega$ and $\Delta$ are intimately related. A similar, but comparatively stronger, correlation was also found for Bi-2212 and PLCCO\cite{14, 17}. Moreover, this mode energy for Nd-123 was observed for only those spectra which exhibit clear PDH features. Thus, the collective mode appears to be intrinsic to the superconducting CuO$_2$ plane. To determine the nature of the observed collective mode, we compare the mode energy with the known phonon energies of Nd-123. The former is rather low compared to the other bosonic modes observed for the cuprates. Thus, the correlation between $\Delta$ and $\Omega$ are qualitatively similar to those observed for Bi-2212, the identification of the nature of this low energy mode in the rare-earth-based cuprate would be important.

In summary, our STS data on as-grown slightly underdoped Nd-123 single crystal do not show any evidence of multiband superconductivity. However, it would be important to probe the CuO$_2$ plane layer in the bulk in order to completely rule out the role of CuO chain band towards superconductivity in these systems. The peak-dip-hump features in the spectra indicate that these are most likely the generic features of the CuO$_2$ plane-derived LDOS in cuprates. Furthermore, a bosonic mode has been detected with a characteristic mode energy of about 23 meV. The mode energy is rather low compared to the other bosonic modes observed for the cuprates. The observed mode energy has certain correlation with the energy gap and thus appears to be intrinsic to CuO$_2$ plane. However, the correlation is weak compared to the ones reported for other cuprates. Thus, the origin of the low energy mode due to a tunneling pathway, which is extrinsic to the CuO$_2$ plane layer, can not be completely ruled out.

[43] Cleaved surfaces of Y-123 mostly expose the CuO chain layer [24,42]. In that case, a direct tunneling to the CuO plane layer, where superconductivity originates, is usually not possible. On the other hand, STS experiments on the as-grown surfaces sometimes reported to have revealed features which are indicative of the CuO plane-derived spectra, see for example Ref. [26,28]. More interestingly, Magio-Aprile et al. have imaged vortices on the as-grown single crystal surface of Y-123, see Ref. [15].
