ABSTRACT

We present a multiwavelength study of a supergiant shell within the violent interstellar medium of the nearby dwarf galaxy IC 2574, which is a member of the M81 group of galaxies. Neutral hydrogen (H i) observations obtained with the Very Large Array (VLA) reveal a prominent expanding supergiant H i shell in the northeast quadrant of IC 2574 which is thought to be produced by the combined effects of stellar winds and supernova explosions. It measures roughly 1000 × 500 pc in size and is expanding at ∼25 km s⁻¹. The H i data suggest an age of ∼1.4 × 10⁶ yr; the energy input must have been of order (2.6 ± 1) × 10⁵³ ergs. Massive star-forming regions, as traced by Hα emission, are situated predominantly on the rim of this H i shell. This supports the view that the accumulated H i on the rim has reached densities that are high enough for secondary star formation to commence. VLA radio continuum observations at λ = 6 cm show that these star-forming regions are the main sources of radio continuum emission in this galaxy. This emission is mainly thermal in origin. Soft X-ray emission from within the H i hole is detected by a pointed ROSAT PSPC observation. The emission is resolved, coinciding in size and orientation with the H i shell. These spatial properties suggest that the emission is generated by an X-ray-emitting plasma located within the H i shell, although a contribution from X-ray binaries cannot be completely ruled out. The X-ray luminosity within the 0.11–2.4 keV energy range is L_X = (1.6 ± 0.5) × 10³⁸ ergs s⁻¹. The X-ray data are compatible with emission coming from a Raymond-Smith plasma at a temperature of about log (T [K]) = 6.8 and a density of n_e ∼ 0.03 cm⁻³. The energy content of the coronal gas corresponds to (4 ± 2) × 10⁵³ ergs, or broadly in agreement with the energy input derived on the basis of the H i observations.

Subject headings: galaxies: individual (IC 2574) — galaxies: ISM — ISM: bubbles — ISM: structure — X-rays: ISM

1. INTRODUCTION

The interstellar medium (ISM) of galaxies is shaped by the aftermath of recent, massive star formation (SF). Huge cavities filled with coronal gas are believed to be blown in the ambient medium through strong stellar winds of the most massive stars as well as through subsequent Type II supernova (SN) explosions of stars more massive than ≈8 M☉ (see Tenorio-Tagle & Bodenheimer 1988 for a review). The structures that form during such processes are often referred to as bubbles (diameter ∼10 pc), superbubbles (∼200 pc), or supergiant shells (∼1 kpc). A recent development is the finding that supergiant shells reach much larger sizes in dwarf galaxies than in more massive spiral galaxies (Puche et al. 1992; Walter & Brinks 1998, hereafter WB98). This is attributed to dwarfs having a lower gravitational potential, which allows shells to grow more easily, and to the absence of differential rotation and spiral density waves, which prevents them from being destroyed prematurely. Dwarf galaxies are therefore ideally suited to study the origin and evolution of supergiant shells.

Cox & Smith (1974) not only realized that the energy input of SNe creates cavities filled with hot gas but that the cooling time is relatively long (10⁶–10⁸ yr, depending on density and temperature of the matter within), which allows the creation of a tunneling network (the Swiss cheese model). Weaver et al. (1977) discussed a model in which fast stellar winds are adiabatically shocked to temperatures of order 10⁸–10⁹ K. These winds then act like a piston, driving the expansion of the outer shell of swept-up ambient material. The basic picture still stands today, although several refinements have been proposed, e.g., by Chu & Mac Low (1990), who calculate the expected X-ray emission from superbubbles.

The ISM that is swept up accumulates in the form of an expanding shell and forms the rim of a superbubble or supergiant shell. The resulting shocks on their rims may induce new generations of SF, or SF regions may be created simply via gravitational fragmentation (Elmegreen 1994; for an early discussion, see Mueller & Arnett 1976).

Direct observational evidence for the theoretical scenarios mentioned above is still scarce. Very few, if any, supergiant shells have been detected to date through the emission of the coronal gas (see Bomans et al. 1996 for a review). In fact, it is the neutral and ionized gas that has proven to be the best tool for tracing the outlines of superbubbles. The best direct evidence has come from ROSAT PSPC observations, which
give information about the plasma properties of the interior of some superbubbles. Examples are the supergiant shell LMC 4 (Bomans, Dennerl, & Küster 1994), the superbubbles N44 (Kim et al. 1998) and N11 (Mac Low et al. 1998), which are all three situated in the Large Magellanic Cloud (LMC), the supergiant shell SGS 2 in NGC 4449 (Bomans, Chu, & Hopp 1997), and the possible supershell near Holmberg IX (Miller 1995). In the following, we will present the probable detection of coronal gas filling a supergiant shell within the nearby (3.2 Mpc) dwarf galaxy IC 2574.

2. OBSERVATIONAL EVIDENCE FOR A HOT GAS-FILLED EXPANDING SUPERGIANT SHELL IN IC 2574

2.1. H I Observations

The neutral interstellar medium of IC 2574 has been extensively studied by WB98 using H I observations obtained with the NRAO\(^1\) Very Large Array (VLA). An H I surface brightness map of IC 2574 is shown in Figure 1 (top left). WB98 find a total of 48 H I holes in IC 2574, most of which are expanding. The most prominent of these holes (number 35 in their study) is the subject of this Letter. An H I map of the region around this hole is shown as a blowup in Figure 1 (middle left). The size of the hole is about 1000 × 500 pc (which corresponds to an effective radius \(r_{\text{eff}} \approx 350\) pc), and its radial expansion velocity is \(\sim 25\) km s\(^{-1}\). The dynamical age is therefore \(\sim 1.4 \times 10^7\) yr. WB98 show that the H I disk is approximately 350 pc, or of the same order as the radius of the hole. Hence, the hole is still contained within the disk (no material lost due to blowout of the gas into the halo). Given the derived scale height and the ambient average H I column density of \(N_{\text{HI}} \approx 10^{21}\) cm\(^{-2}\), the ambient H I volume density before the creation of the hole is estimated at \(n_{\text{HI}} = 0.5\) cm\(^{-3}\). The H I mass that was present before the evacuation of the H I hole, which now must be largely accumulated on the rim, is therefore \(\sim 2 \times 10^6\) \(M_\odot\). Using these numbers and correcting the H I mass for the contribution of primordial helium, we estimate the kinetic energy of the expanding shell to be \(\approx 1.7 \times 10^{52}\) ergs.

No signature of an infalling high-velocity cloud is found in the H I data, and WB98 propose an internal origin for the creation of the hole. Using the numerical models of Chevalier (1974), who calculates the late phase of supernova remnants in which the shell accretes matter from both the interstellar medium and the hot interior, an energy input of \((2.6 \pm 1) \times 10^{53}\) ergs by a star-forming region is needed to create this hole. Note that the kinetic energy of the hole is of order 10% of this value, which is about half of the value originally predicted by Weaver et al. (1977). This energy is equivalent to \(\approx 100\) Type II SNe and the strong stellar winds of their progenitors—a major SF event.

2.2. Hα Observations

In order to trace regions of current SF activity, Hα maps were obtained by WB98. A gray-scale representation of their Hα map is given in Figure 1 (top right). Although the global SF activity in IC 2574 is rather low, a ring of H II regions is prominent in the northeast quadrant of the galaxy. A blowup of the Hα emission around the same region as in the middle left-hand panel of Figure 1 is given in the middle right-hand panel. Note that virtually all Hα emission in that region is situated on the rim of the H I shell (as first noticed by Martimbeau, Carignan, & Roy 1994). Three Wolf-Rayet stars have been detected in the most luminous H II region on the northern rim by Drissen, Roy, & Moffat (1993). IUE spectra through the same region show the presence of P Cygni profiles, indicating the presence of strong stellar winds (Rosa, Joubert, & Benvenuti 1984). Using the calibration by Miller & Hodge (1994), the total Hα flux on the rim is \(2.3 \times 10^{-12}\) ergs cm\(^{-2}\) s\(^{-1}\), which corresponds to a luminosity of \(L(\text{Hα}) = 7 \times 10^5 L_\odot (L_\odot = 3.85 \times 10^{38}\) ergs s\(^{-1}\)) or an energy equivalent of \(\approx 50\) stars of spectral type O5 (WB98). This is almost one-third of the Hα luminosity of 30 Dor, which is believed to be the most active SF region in the Local Group (Chu & Kennicutt 1994). The average volume densities derived on the rim of the shell are 3 cm\(^{-3}\) for the neutral H I (southern part) and 2 cm\(^{-3}\) for the ionized hydrogen in the northern part. This suggests that most of the neutral gas component in the northern part of the hole has been ionized by the prominent SF regions.

2.3. Radio Continuum Observations

Radio continuum maps of IC 2574 were obtained at \(\lambda = 6\) cm using the VLA D array. A map of the \(\lambda = 6\) cm emission is presented in Figure 1 (bottom right). We detect four radio sources in the region of the supergiant shell; their positions and flux densities (in parentheses) are B102459.7+684320 (S = 0.9 mJy), B102503.1+684348 (S = 1.1 mJy), B102507.5+684325 (S = 0.8 mJy), and B102507.7+684346 (S = 0.8 mJy). The flux densities are accurate to within 20%. Three of the four sources coincide with regions of intense Hα emission on the rim of the shell. These sources have radio/Hα flux ratios that are consistent with the radio emission being purely thermal (Caplan & Deharveng 1986). This result confirms that the Hα emission traces photoionized gas and that these sources are indeed H II regions and not shock-ionized regions formed by the expansion of the hole.

The source furthest to the southwest, B102459.7+684320, is clearly nonthermal (see Fig. 1, bottom right), and its radio emission is well in excess of what one would expect from an H II region on the basis of the rather weak Hα emission. It most likely is a supernova remnant given its nonthermal nature, its appearance as a point source and a flux density that is consistent with the brighter SN remnants found in nearby galaxies (e.g., Duric et al. 1995; Lacey, Duric, & Goss 1997).

2.4. X-Ray Observations

In order to examine the X-ray properties of IC 2574, we have analyzed a ROSAT PSPC observation toward IC 2574 (US600145P; total integration time 7.3 ks). The PSPC point-spread function at \(E = 1.23\) keV is \(\approx 28\)” (FWHM) across the area of interest. The pointed ROSAT PSPC observation reveals a significant X-ray feature that is coincident with the very center of the H I hole. A contour map of the X-ray emission is overlaid on the Hα-emission in Figure 1, top right-hand panel (whole galaxy) and middle right-hand panel (blowup). An overlay with the H I is presented in Figure 1 (bottom left). This X-ray feature has an angular extent of \(\approx 45\” \times 30\”\) (FWHM), with its major axis aligned with the H I hole. Note that the emission is extended even if we account for the residual pointing uncertainties of the ROSAT” telescope of \(\sim 10\”\) (G. Hasinger 1997, private communication). In addition, ROSAT’s wobble direction during

\(^1\) The National Radio Astronomy Observatory (NRAO) is operated by Associated Universities, Inc., under cooperative agreement with the National Science Foundation.
the observations was perpendicular to the orientation of the major axis of the H I hole. Based on the ROSAT PSPC observations, we therefore find evidence for extended X-ray emission originating from the interior of the H I hole. However, higher resolution observations will be needed to confirm this.

IC 2574 is located at a high Galactic latitude ($b \approx +43^\circ$), which means that the photoelectric absorption due to the Galactic interstellar medium is moderate. The Leiden/Dwingeloo H I $\lambda = 21$ cm line survey (Hartmann & Burton 1997) gives an H I column density of $N_{\text{HI}} = 2 \times 10^{20}$ cm$^{-2}$ after separating the Galactic diffuse H I emission from that of IC 2574. Because of the apparently clear line of sight through the hole (see Fig. 1, top left), we considered it justified to neglect any contribution to the H I column density within IC 2574.

To separate the source counts from that of the diffuse X-ray background, we performed an on/off analysis. This method also removes the contribution of the so-called non-cosmic X-ray background radiation (Snowden et al. 1994). In order to obtain quantitative information about the spectrum of the X-ray feature, we evaluated the standard ROSAT hardness ratios (HR1
and HR2), which range from −1 (soft) to 1 (hard). We took this approach because the number of photons is too low for a standard analysis of the X-ray spectrum. We divided the ROSAT energy band into the three main energy bands, denoted as ROSAT C band (0.25 keV, PI channels 11−41), the M band (0.75 keV, 52−90), and the J band (1.5 keV, 91−201). The evaluation of HR2, which is nearly unaffected by Galactic absorption, yields a value of \( \text{HR2} = (J - M)/(J + M) = 0.2 \pm 0.2 \). This leads to a first estimate of the temperature of \( \log (T/[\text{K}]) \approx 6.8 \). Adopting this estimate, we can correct the soft bands for photoelectric absorption by the Galactic ISM (Snowden et al. 1994). This analysis yields \( \text{HR1} = (J + M - C)/(J + M + C) = 0.2 \pm 0.4 \) and the following photon counts for energies below and above 1 keV: \( \langle E < 1 \text{ keV} \rangle = 106 \pm 39 \) and \( \langle E > 1 \text{ keV} \rangle = 38 \pm 9 \) counts. This simple approach indicates that the X-ray feature emits most of its photons below \( E = 1 \text{ keV} \). Combined with the fact that the source is elongated, this suggests that a high-mass or most of its photons below keV. Combined with the fact that the source is elongated, this suggests that a high-mass or higher abundance is \( \log ([\text{K}]) \). Note that a higher abundance is \( \log ([\text{K}]) \approx 0.4 \) for the coronal gas filling the hole, we derive an internal pressure of \( P = 2n_{\text{in}}T \approx (4 \pm 2) \times 10^5 \text{ K cm}^{-3} \) (LMC 4: \( P = 2 \times 10^4 \text{ K cm}^{-3} \)). This value has to be compared to the much lower pressure of the ambient warm ionized medium \( (P \approx 10^3 \text{ K cm}^{-3}) \). This means that it is probably this hot gas that is still driving the expansion of the shell (see, e.g., Weaver et al. 1977).

The shell, as it is swelling up material, has already reached the point at which secondary star formation can take place, as evidenced by the H II regions located along its periphery. The energy of the hot gas interior can be approximated by \( 3/2(n_P)n_PkT \) and yields a value of \( (4 \pm 2) \times 10^{53} \text{ ergs} \). The model by Weaver et al. (1977) predicts that \( \sim 50\% \) of the total energy deposited by SNe is converted into thermal heating of the gas within the created superbubble. Our values indicate that, within the errors, most of the energy deposited by the SN explosions has indeed gone into the heating of the gas. Note that a small decrease in temperature and increase in the ambient density would bring these numbers in even closer agreement. In fact, it is the broad agreement of the observed numbers with those derived from theory that gives us added confidence that it is indeed hot diffuse gas that fills the cavity rather than a cluster of X-ray binaries. A definitive answer will have to await the better spectral and spatial resolution of future X-ray missions, such as the Advanced X-Ray Astrophysics Facility and X-Ray Multimirror Mission, which are expected to shed further light on this unique object.
