ABSTRACT: Linear polyethylenimine (L-PEI), a standard for nonviral gene delivery, is usually prepared by hydrolysis from poly(2-oxazoline). Lately, anionic polymerization of sulfonylamide-activated aziridines had been reported as an alternative pathway toward well-defined L-PEI and linear polyamines. However, desulfonylation of the poly(sulfonyl aziridine)s typically relied on harsh conditions (acid, microwave) or used a toxic solvent (e.g., hexamethylphosphoramide). In addition, the drastic change of polarity requires solvents, which keep poly(sulfonyl aziridine)s as well as L-PEI in solution, and only a limited number of strategies were reported. Herein, we prepared 1-(4-cyanobenzenesulfonyl) 2-methyl-aziridine (1) as a monomer for the anionic ring-opening polymerization. It was polymerized to well-defined and linear poly(sulfonyl aziridine)s. The 4-cyanobenzenesulfonyl-activating groups were removed under mild conditions to linear polypropylenimine (L-PPI). Using dodecanethiol and diazabicyclo-undecene (DBU) allowed ≥98% desulfonylation and a reliable purification toward polyamines with high purity and avoiding main-chain scission. This method represents a fast approach in comparison to previous methods used for postpolymerization desulfonylation and produces linear well-defined polyamines. The high control over molecular weight and dispersities achieved by living anionic polymerization are the key advantages of our strategy, especially if used for biomedical applications, in which molecular weight might correlate with toxicity. The synthesized polypropylenimine was further tested as a cell-transfection agent and proved, with 16.1% transfection efficiency of the cationic nanoparticles, to be an alternative to L-PEI obtained from the 2-oxazoline route. This general strategy will allow the preparation of complex macromolecular architectures containing polyamine segments, which were not accessible before.
copolymers of aziridines with styrene or lactide were also prepared recently, relying on sequent.

Even though poly(sulfonyl aziridine)s could be beneficial materials for several applications, in which hydrophobicity or high thermal resistance might be beneficial, to date they are mainly considered as intermediates to polyamines after removal of the sulfonyl groups. Linear polyethylenimines (L-PEIs) of well-defined size and dispersity are important for nonviral gene transfection. L-PEI is also used in applications such as antifouling coatings, chelation, or for CO2 capture. However, only a limited number of synthetic strategies give access to L-PEI: the cationic ROP (CROP) of aziridines only provides branched polymers, and probably the most common pathway toward L-PEI is the acidic or basic hydrolysis of poly(2-oxazoline)s. The synthesis of poly(2-oxazoline)s was developed more than 50 years ago and was continuously improved. Today, CROP of 2-oxazolines can be conducted as living cationic polymerization, providing well-defined polymers with low dispersities. Other methods are rare, and one to be mentioned is the mild acidic hydrolysis of poly(N-pyrranyl ethylenimine)s. However, as the CROP suffered from chain transfer and termination reactions, this strategy was not further continued.

Herein, we developed a strategy based on living anionic ROP to linear polyamines. LAP avoids termination reactions and gives access to complex polymer architectures. Several monomer classes are polymerized by LAP, and aziridines might be a powerful addition to the monomer set for additional complex structures. Sulfonyl aziridines gave access to polyamines by different desulfonylation strategies. However, the need for toxic solvents or harsh reaction conditions (e.g., highly acidic, microwave, or lithium metal in HMPA) made this strategy less attractive compared to the oxazoline route. Additionally, chain scission had been reported, and the workup procedures reduced yields in some cases.

Sulfonamides, however, have adjustable stability depending on their substitution pattern, which can be utilized to tailor desulfonylation conditions. While tosyl groups need strong acids or reducing conditions to be removed from the polymer, desulfonylation of nitrophenylsulfonyl groups had been removed under much milder conditions, recently. However, the purity and yield of the obtained L-PEI were lower compared to L-PEI from poly(2-oxazoline)s. Further, the nitrophenylsulfonyl-activated monomer proved to be highly reactive, and spontaneous polymerization was reported.

Here, we present the synthesis and polymerization of the activated sulfonyl aziridine 1 (Scheme 1). The monomer 1 was prepared by the reaction of 2-methyl-aziridine with 4-cyanobenzenesulfonyl chloride and purified crystallization from tert-butyl methyl ether. The monomer was obtained as a white powder with a 93% yield and was bench-stable over several weeks without polymerization.

The 1H NMR spectrum of 1 revealed the typical resonance pattern for a 2-substituted sulfonyl aziridine with resonances from 3.53 ppm (m), 2.24 ppm (d), and 1.34 ppm (d) (Figure S1). In the 13C NMR spectrum, the resonances of the ring carbons were detected at 36.8 and 35.6 ppm, respectively, indicating a stronger electron-withdrawing effect of the cyanobenzenesulfonyl group compared to other sulfonyl aziridines (Figure S2, note: the tosyl-substituted analogue exhibited 13C NMR resonances at higher field (ca. 35.9, 34.7 ppm)). ESI mass spectrometry proved the successful preparation of 1 with a single mass peak for the protonated monomer at 223.1 Da (MH+, Figure S3). For the polymerization of 1, the monomer was freshly recrystallized and dissolved in DMF at 50 °C, and the initiator solution was added. The polymers were purified by precipitation from the crude reaction mixture into cold methanol or diethyl ether with yields of 86–96%. Polymers with degrees of polymerization (DP) from 25 to 200 repeating units, Mn = 6300–44 700 g mol−1 were synthesized with narrow to moderate molecular weight distributions (Đ = 1.15–1.43, Figure 1 and Table 1). The increased molar mass dispersities with an increasing degree of polymerization might be caused by decreased solubility of the polymers as we had encountered for previous poly(sulfonyl aziridine)s. 1H NMR spectroscopy proved the successful formation of the polymer, with typical resonances for poly(sulfonyl aziridine)s (cf. Figure 2 and labels in the spectra).

### Table 1. Molar Mass Characterization of Different Polymers Based on Monomer 1

| Monomer | DP | Mn/g mol−1 | Mw/g mol−1 | Đ |
|---------|----|------------|------------|---|
| Poly1   | 200 | 44 700 d   | 8600 d     | 1.43 d |
| Poly2   | 90  | 20 500 a   | 6500 a     | 1.14 a  |
| Poly3   | 79  | 17 500 a   | 5200 a     | 1.18 a  |
| Poly4   | 42  | 9300 a     | 3500 a     | 1.15 a  |
| Poly5   | 30  | 6300 a     | 1900 a     | 1.12 a  |
| PPI-1   | 215 | 12 400 a   | 17 800 a   | 1.22 a  |
| PPI-2   | 83  | 5000 a     | 12 100 a   | 1.29 a  |
| PPI-5   | 30  | 1800 a     | 5 600 a    | 1.16 a  |

*a Determined via 1H NMR. b Determined via SEC (DMF vs PEO standards). c Determined via SEC in hexafluoroisopropanol (HFIP). d Theoretical value.

![Figure 1. SEC elugrams of Poly1–Poly5 (in DMF, RI detection).](image-url)
The polyamines were released by a mild desulfonylation via a nucleophilic attack to the electron-deficient 4-cyanophenylsulfonyl group by a thiolate forming a Meisenheimer complex (Scheme 2). Desulfonylation was performed in DMF with a 5-fold excess of 1-dodecanethiol and DBU as a base (note: the cyanobenzenesulfonyl groups can be removed directly after the polymerization by adding DBU and the thiol or after workup of the intermediate poly(sulfonyl aziridine)).

Linear polypropylenimine (L-PPI) was isolated after the addition of ethyl acetate to the crude mixture and extraction with water. L-PPI was obtained after subsequent dialysis and lyophilization with ca. 40% yield. As the desulfonylation occurred under very mild conditions, also the SEC traces of the linear PPIs exhibited narrow molar mass dispersities, comparable to the starting materials. In addition, the fluorescent initiator remained intact (Scheme 2A), proving the possibility to install further functionalities at the α-position of the polymer chain end. The PPIs (1, 2, and 5) are eluted at earlier elution volumes compared to the precursors Poly1, Poly2, and Poly3 (compare SEC in HFIP, Figures S4 and S5), which is probably related to a larger hydrodynamic radius than the precursor polymer in HFIP. The desulfonylation was reproducible also for high molar mass PPIs (Table 1, PPI-1), indicating that during the process chain scission was avoided.

The purified L-PPI was analyzed by 1H NMR (Figures 2 and S6) and 13C NMR spectroscopy (Figure S7) proving that a high to quantitative desulfonylation of at least 98% was achieved. Similar values are reported for the hydrolysis of commercially available L-PEI from poly(2-oxazoline)s with 92–93% hydrolysis.27 Laboratory-produced L-PEI from poly(2-oxazoline)s with 99% to quantitative hydrolysis efficiency for L-PEI was reported,27 similar to the herein reported L-PPI from poly(sulfonyl aziridine)s. MALDI ToF MS of PPI-2 (Figure S8) underlines the effective desulfonylation. All the main signals in the spectrum were attributed to PPI, confirming the removal of the cyanobenzenesulfonyl groups and showing only the repeating unit of propyleneimine (with 57.1 g mol\(^{-1}\)). Other peaks for molar masses referring to the partly deprotected polymer were not detected. Compared to the results of SEC and 1H NMR, the MALDI ToF MS analysis underestimated the mass of the polymer, and only smaller fractions of polyamine were detected, which is probably due to mass discrimination effects. It was reported that the multiple charges on polyamines resulted in complexation to impurities during the sample preparation and adhesion to the metal substrate, thus reducing the resolution of mass spectra.34

The linear PPI-5 was used to study cellular transfection efficiency. The gene-loaded cationic PPI-5 nanoparticles (abbreviated as PPI5-DNA-NPs below) were obtained by means of electrostatic attraction between the anionic plasmid DNA and the cationic PPI. Figure S9 shows the representative size distribution profiles and zeta potentials of the nanoparticles. The particle size and polydispersity index of PPI5-DNA-NPs (N/P = 40) were 89 nm and 0.206, respectively, demonstrating a relatively narrow particle size distribution. In addition, as N/P increased, the surface charges with zeta potentials changed from −20.8 to 24.5 mV were measured. The results of agarose gel electrophoresis (Figure S10) proved that PPI5-DNA-NPs bind with DNA to various degrees with different N/P ratio in the complex. There was decreasing free...
DNA present in the lane with the increase of the ratio of PPI5/DNA. When the N/P of NPs reached 20:1 or above, almost all DNA was combined with NPs without free DNA bands in the visible lane. Detection of the expression of EGFP was carried out using an inverted fluorescent microscope (Figure S12) and flow cytometry (Figure 3). The results underlined that PPI5-DNA-NPs successfully transferred plasmid DNA into 293T cells, and the transfection efficiency can reach 16.1% when the N/P of PPI5-DNA-NPs is 50:1 (Figure 3). To the best of our knowledge, this is the first example for a gene transfection conducted with a polyamine, prepared from poly(sulfonyl aziridine)s.

In summary, we presented a novel activated sulfonyl aziridine, 1, a monomer for the anionic ring-opening polymerization. Similar to other monomers of the family of sulfonyl aziridines, well-defined linear poly(sulfonyl aziridine)s were obtained by ROP. In contrast to previously reported highly activated aziridines, 1 was bench stable and did not undergo spontaneous polymerization. More importantly, mild desulfonylation via a nucleophilic aromatic substitution removed the 4-cyanobenzenesulfonyl groups almost quantitatively, and linear polypropylenimines were obtained. We believe this strategy is to date the fastest and mildest pathway to well-defined linear polyamines. The reaction conditions avoid very low or high temperatures, harsh reaction conditions, and toxic solvents (such as HMPA) and exhibit an easy workup procedure, to access linear polyamines by anionic ring-opening polymerization, which further allows the combination with other anionic polymerization techniques for macro-molecular architectures. We further demonstrated the successful application of PPI as a cell transfection agent; the cationic L-PPI can bind DNA through electrostatic attraction, and the gene vectors PPI5-DNA-NPs were used successfully to transfer the reporter gene EGFP to 293T cells, leading to gene expression and subsequent protein synthesis. We believe this general strategy will broaden the synthetic toolbox for the preparation of complex macromolecular architectures containing well-defined polyamine segments.
