A B S T R A C T
Antibiotic-resistant pathogens constitute an escalating public health concern. Hence a better understanding of the underlying processes responsible for this expansion is urgently needed. Co-selection of heavy metal/biocide and antibiotic resistance genes (ARGs) has been suggested as one potential mechanism promoting the proliferation of antimicrobial resistance (AMR). This paper aims to elucidate this interplay and exploit differences in antibiotic usage to infer patterns of co-selection by the non-antibiotic factors metals and biocides in the context of pig farming. We examined 278 gut metagenomes from pigs with continuous antibiotic exposure, only at weaning and at no exposure. Metals as growth promoters and biocides as disinfectants are currently used with little restrictions in stock farming. The pigs under continuous antibiotic exposure displayed the highest co-occurrence of ARGs and other genetic elements while the pigs under limited use of antibiotics still showed abundant co-occurrences. Pathogens belonging to Enterobacteriaceae displayed increased co-occurrence phenomena, suggesting that this maintenance is not a random selection process from a mobilized pool but pertains to specific phylogenetic clades. These results suggest that metals and biocides displayed strong selective pressures on ARGs exerted by intensive farming, regardless of the current use of antibiotics.

1. Introduction
Antimicrobial resistance in pathogenic bacteria constitutes a considerable public health concern (Baker-Austin et al., 2006). Despite making tremendous efforts to restrict usage of several key antibiotics worldwide, AMR can frequently be found in different environments (B. Li et al., 2015; Rodriguez-Mozaz et al., 2015). To control the potential threat from AMR spread, it is necessary to investigate the underlying processes responsible for this expansion.

Generally, the occurrence of AMR is largely driven by the selection pressure of antibiotics (Aarestrup, 2012). Besides that, other agents such as antibacterial biocides and heavy metals can help to maintain AMR via co-selection (Ashbolt et al., 2013; Ding et al., 2019; Hartmann et al., 2016; Mazhar et al., 2021; Wang et al., 2021; Zhang et al., 2020). The co-selection of ARGs and metal resistance genes (MRGs) has been commonly observed in contaminated soil (Song et al., 2017), water (İcgen and Yılmaz, 2014), and industrial environments (Mazhar et al., 2021; Stepanauskas et al., 2005) with enriched metals. Some literature has demonstrated that ARGs had a stronger correlation to some metals than to their corresponding antibiotics (Ji et al., 2012). Unlike antibiotics, metals can constitute a long-term selection pressure due to metals not being degradable (Stepanauskas et al., 2005), which can bring stability to the ARG pool in both engineered and natural systems. Compared to metals, biocides have received less attention as a potential co-selection agent. Biocide substances have been employed for centuries as disinfectants for medical equipment and as preservatives in pharmaceuticals, cosmetics and food (SCENIHR, 2009), especially biocides with limited toxicity to animals such as quaternary ammonium compounds (QACs), biguanides and bisphenols (Granada Burgos et al., 2013). However, some research has suggested excessive use of QACs increased bacterial tolerance to antibiotics (Buffet-Bataillon et al., 2012; Tandukar et al., 2013). Metals and biocides can co-select for antibiotic-resistant
bacteria by several mechanisms (Chapman, 2003): resistance genes are physically located on the same genetic element (co-resistance); the same gene confers resistance to both antibiotics and biocide/metal (cross-resistance); biocide resistance genes (BRGs)/MRGs share the same regulatory mechanism with ARGs (co-regulation).

The concurrent transfer of ARGs and BRGs/MRGs via mobile genetic elements (MGEs) may be another potential challenging public health problem, which has aggravated the persistence and spread of ARGs (Yu et al., 2016; Zhao et al., 2019). So far, research on the co-transfer of these three genetic determinants has been limited, although there are plenty of opportunities for this to occur. Stock farming is one such potential hot spot for the dissemination of combinations of ARGs, BRGs/MRGs, and MGEs due to the widespread use of antibiotics, heavy metals and biocides in food feed (Clark, 2004). Pigs represent the largest livestock category in the EU and have also extensively served as a major biomedical model for human biology (Lunney, 2007). Antibiotics (Gaskins et al., 2002) and metals (especially zinc and copper) (Fengresistance); biocide resistance genes (BRGs)/MRGs share the same regulatory mechanism with ARGs (co-regulation). The antibiotic usage patterns in the co-selection of heavy metals/biocides and antibiotics used in animal control of bacterial resistance (Xiao et al., 2016). The antibiotic usage patterns in the co-selection of heavy metals/biocides and antibiotics used in animal farming, which are closely connected to human health, are still scarce (Seiler and Berendonk, 2012), especially under various exposure levels of antibiotics. In livestock production, pigs are given the highest amount of copper and zinc making it a very suitable system to study co-selection (Rensing et al., 2018).

Genome sequencing has often complemented analysis of phenotypic outcomes (Song et al., 2017; Stepanauskas et al., 2006) to clarify the genetic determinants of resistance, and indeed large-scale efforts have investigated repositories of publicly available genomic data and established the co-presence of both metal- and antibiotic-resistance (Li et al., 2017; Pal et al., 2015). These repositories are comprehensive, but the information about the origins of the sequenced isolates varies, making it difficult to infer that genes of interest are present in the underlying populations as a whole. In this study, we attempted to make use of publicly available metagenomics data of 278 pigs in the different farms from three countries (Xiao et al., 2016). The antibiotic usage patterns in these pigs have been well-characterized. The use of antibiotics on pig farms varies from country to country, but metals and biocides were used in all farms. We hypothesized that biocide and metal resistance genes would co-localize with ARGs, resulting in the selection pressure on ARGs in pig guts independent of antibiotic usage.

2. Methods
2.1. Sample information, data collection and pre-processing

Table S1 illustrates the antibiotic exposure on 278 pigs in different farms (Xiao et al., 2016). Seventy-eight pigs in the Chinese farm were continuously exposed to various antibiotics, while one hundred pigs in Danish farms were only exposed at weaning. One hundred pigs in French farms were raised completely organic, although a subset of them was raised on farms with previous use of antibiotics.

The clean Illumina Hiseq paired reads of 278 pig gut metagenomes were retrieved at https://www.ebi.ac.uk/ena/data/view/PRJEB11755 from European Bioinformatics Institute (EBI). The adaptor contamination, low-quality reads and pig genomic DNA have previously been removed in clean data. Assembly of contigs was done with megahit (version 1.1.3) with default options (D. Li et al., 2015). Any contigs shorter than 500 bp were filtered out. The prediction of open reading frame (ORF) in the contigs was performed with prodigal (version 2.6.2) in META mode (Hyatt et al., 2010).

2.2. ARG, BRG, MRG, and MGE predictions

The antibacterial biocide and metal resistance genes database (BacMet, version 2.0) was used for the predictions of BRG and MRG (Pal et al., 2014): the amino acid sequences of predicted ORFs were subjected to similarity searches against the BacMet database with diamond search (version 0.3.3.1b2) with an E-value of 10⁻² were retained. The Comprehensive Antibiotic Resistance Database (CARD database, version 3.0.0) was used to detect ARGs: the amino acid sequences of predicted ORFs were aligned with the CARD database through RGI identifier with diamond as aligner (Jia et al., 2017). Only ARGs with “Strict” or “Perfect” significance cut-off were preserved for further analysis. MGE homologs were characterized using PPFAM (Finn et al., 2016) and TnpPred (Riadi et al., 2012) databases through HMMER (McMurdie and Holmes, 2013). Permutation multivariate analysis of variance (PERMANOVA) was used to compare the differences in β-diversity between groups when FDR correction was required (R function “pairwise.adonis” in R) (Arbuzov, 2017). Within-individual diversity (α-diversity) was measured by observed richness of gene coverage/abundance. One-way ANOVA (R package “stats”) was used to compare the differences in α-diversity among groups. TukeyHSD test (R package “stats”) was used to do pairwise comparisons of α-diversity. The pairwise comparison of gene abundance between three groups was done using the Wilcoxon rank sum test (R function “pairwise.wilcox.test”). Venn diagram was plotted using R function “draw.triple.venn” in R package “VennDiagram” (Chen and Boutros, 2011). Fisher’s exact test was used to test the statistical significance of the number of contigs between groups (R function “fisher.test” in R package “stats”).
2.5. Co-occurrence analysis

The study from the reference genomes. A minimal blast similarity of 95%, a search for the contigs carrying ARGs, MGEs, BRGs/MRGs detected in the BLAST database with makeblastdb. Blastn (version 2.6.0) was used to and the downloaded bacterial genomes were indexed to generate a considered as co-occurring. Co-occurrence was considered trustable if the same association was present in at least two different contigs.

2.6. Contig source screening

Fifteen million contigs from 138,683 bacterial genomes in the NCBI Reference Sequence Database (RefSeq) were downloaded (19.12.2018) and the downloaded bacterial genomes were indexed to generate a BLAST database with makeblastdb. Blastn (version 2.6.0) was used to search for the contigs carrying ARGs, MGEs, BRGs/MRGs detected in the study from the reference genomes. A minimal blast similarity of 95%, a shortest alignment length of 10 kb and a biggest E-value of 10^-9 were used to filter blast hits. R function “heat tree” in “metacoder” package (Foster et al., 2017) was used to plot the taxonomic tree to visualize the bacterial contig source. The tree branch represents the affiliation relation between taxa.

3. Results

3.1. Gut microbiome of pigs in the Chinese farm contained the highest abundance of resistance genes

The total loads of BRGs, MRGs, and potentially mobile ARGs (ARGs found together with MGEs in one contig) varied significantly between different farms (Fig. 1A). When looking at all resistance determinants, the gut microbiome of pigs in the Chinese farm carried the highest load (Pairwise Wilcoxon rank-sum test, FDR-adjusted \( P < 0.05 \)). The pigs in Danish farms had the second-highest abundance of mobile ARGs (FDR-adjusted \( P < 0.05 \)) and similar abundance of BRG as in the pigs in French farms (FDR-adjusted \( P = 0.53 \)). The pigs in French farms had the second-highest abundance of MRGs (FDR-adjusted \( P < 0.05 \)). Notably, only 10 of 100 pigs in French farms had mobile ARGs in their gut microbiome, though the total abundance of MGEs in French pigs was similar to Chinese pigs.

We calculated observed richness for each resistance determinant in different farms (Fig. 1B). For each gene type, pigs in the Chinese farm were found to have a higher diversity followed by the pigs in Danish farms (TukeyHSD test; \( P < 0.05 \)). However, pigs in French farms had similar BRG (\( P = 0.11 \)) and MRG (\( P = 0.08 \)) diversity compared to pigs in Danish farms.

In general, mobile ARGs, BRGs, MRGs and MGEs displayed significant differences in composition based on farms (Fig. 1C) (pairwise Adonis test, FDR-adjusted \( P < 0.05 \)). In total, the detected ORFs conferred resistance to 20 metals, 36 biocides, 34 antibiotics, and encoded 8 types of mobile genetic elements. Fig. 1D shows the most abundant genes conferring resistance to 15 metals, 14 biocides, and 11 antibiotics. Overall, of the MRGs detected, genes conferring Zn and Cu resistance were the most abundant. Among BRGs, genes encoding resistance to QACs were the most abundant. When we investigated the potentially mobile fraction of the ARG pool, lincomamide and tetracycline resistance genes were found to be the most abundant and the transposases to be the most common trait related to mobility mode.

3.2. Surveying assembled contigs carrying co-occurrence of ARGs and BRGs/MRGs/MGEs

We then investigated the co-occurrence of resistance genes on contigs, in the categories of ARGs, BRGs/MRGs, and MGEs to evaluate the potential for co-selection (Fig. 2A). Evidently, the pigs in the Chinese farm had the largest amount of overlap from different categories, with 61 contigs harboring all 3 different categories of genes, while this was not observed in any of the pigs in French and Danish farms. MGEs were the largest category and had ample overlap with other categories. The pigs in the Chinese farm had the highest proportion of contigs carrying multiple co-occurrences (Fig. 2B) (Fisher’s exact test; \( P < 0.05 \)). The pigs in French farms had a significantly higher proportion of contigs with ARGs and BRGs/MRGs than the pigs in Danish farms (\( P < 0.05 \)). In contrast, the pigs in Danish farms had a higher proportion of contigs carrying resistance genes together with MGEs than the pigs in French farms (\( P < 0.05 \)). Compared to BRGs/MRGs, a larger proportion of ARGs generally tended to sit together with MGEs in the same contigs (Fisher’s exact test; \( P < 0.05 \)) (Fig. 2C).

3.3. Visualization of the assembled contigs carrying ARGs and other genes

To further verify the co-occurrence of ARGs and BRGs/MRGs/MGEs on the contigs, we visualized the gene organization on representative contigs (Fig. 3A). According to resistances carried in each representative contig, there were six major co-occurrence combinations and 27 co-occurrence subtypes. We selected the contig carrying the most complete gene distribution in each of 27 subgroups as the representative contig. All the co-occurrences involved 131 resistance genes to 17 metals, 28 biocides and 25 antibiotics. Of these, Cu, Ni and Zn resistance genes, fluoroquinolone, penam and tetracycline resistance genes, acid and QAC resistance genes were the most co-occurring genes. The information about these genes has been summarized in Table S2.

Co-occurrences in the pigs from the Chinese farm were detected to be most common, in terms of both the number of contigs carrying co-occurrences and the type of co-occurrence (Fig. 3A). We identified all 27 co-occurrence subtypes in the Chinese farm, 20 subtypes in French farms, and 9 subtypes in Danish farms. Some co-occurrences affiliated with the same subtype were only partly present in the presentative contig. Therefore, to further investigate the abundance of co-occurrences, we plotted a network to show the frequency of co-occurrences between resistance genes in all the contigs (Fig. S1). The detailed information for the network has been summarized in Table S3. As shown in Fig. S1, ARGs in the pigs from Danish farms mostly co-occurred with BRGs, which mostly tended to be genetically linked, such as multidrug efflux transporter genes acrAB and its regulator gene acrR. Notably, we detected an assembled contig carrying one colistin resistance gene MCR-4 and Cd/TBT resistance gene qglW in the pigs from Danish farms.

Some co-occurrences were only detected in the pigs from the Chinese farm (Fig. 3A) – for example, the co-occurrence of fluoroquinolone ARG CRP with the Ni resistance operon nika/B/C/D/E/R and Zn resistance gene zntA (II); the co-occurrence of aminoglycoside ARG kdpE with nine Cu resistance genes cusA/C/B/F/R/S, cutEF, corC (I); and the co-occurrence of streptogramin ARG vgac with seven Cu resistance genes pcoA/B/C/D/E/R/S (III). Two archetypal class I clinical integrons carrying 3 conserved segment (CS) of an antiseptic-resistance gene qaceA1, a sulfonamide resistance gene sul1, 5 CS of the integrase, as well as gene cassettes adaA2-dfrA12 (Integron A, XXIV) or an IS6 transposase gene (Integron B, XXV) were only detected in the pigs from the Chinese farm. An analogous structure consisted of qaceF, sul3, an integrase, and gene cassette dfrA12-adaA2-cmlA6-adaA1 was only detected in the pigs from the Chinese farm as well (Integron C, XXVII). To verify whether these three integrons have ever been located on plasmids, we mapped the three representative contigs against the Plasmid pIsm2 plasmid database (Galata et al., 2019). It turned out that Integron C and Integron B were very similar to DNA fragments in 180 and 73 plasmids, respectively (Mash search, Max distance = 0.1) whereas Integron A did not have any hits. Integron C was frequently found in E. coli, Klebsiella pneumonia and Salmonella enterica (Fig. S2-a and Table S4). The bacteria harboring Integron B covered a wide range of species such as E. coli, Pseudomonas aeruginosa, Klebsiella pneumonia and Enterobacter cloacae (Fig. S2-c and Table S5). The gut microbiome in the pigs from the Chinese farm harbored some co-occurrences related to polymyxin including colistin resistance genes. For example, the polymyxin ARG ugd was located in the same contig with Co-Ni-Fe related resistance genes rcaA/B/R,
Fig. 1. Overview of MRGs, BRGs, mobile ARGs, and MGEs in pig gut microbiomes from different farms. A). Violin plot showing the total abundance of resistance genes and MGE per sample. White lines represent the median. Asterisks stand for significant statistical difference between groups (Pairwise Wilcoxon rank-sum test, FDR-adjusted; $P < 0.05^*$, $P < 0.01^{**}$, $P < 0.001^{***}$, NS: $P > 0.05$). B). Violin plot showing the observed richness of resistance genes and MGE. White lines represent the median. Asterisks stand for significant statistical difference between groups (TukeyHSD test; $P < 0.05^*$, $P < 0.01^{**}$, $P < 0.001^{***}$, NS: $P > 0.05$). C). PCoA plots showing Bray-Curtis distances of mobile ARG, BRG, MRG and MGE among pigs from Chinese, Danish and French farms. D). Average abundance of resistance genes and MGE in the different countries. The abundance of multiple resistance genes was separately counted in the individual functional group; for example, the gene with AMR and biocide resistance (BR) was included both in AMR and BR abundance plots. Labels on the stacked bars describe the metals and biocides associated with BRGs and MRGs, different drug classes associated with mobile ARGs and 8 categories of MGEs. The height of the stacked bars represents the mean value of the total abundance in the log scale.
multidrug efflux system MdtA/B/C, BaeS/R two-component system (VII); Polymyxin resistance genes pmrA/B/C, colistin heteroresistance related aoxR/S, co-occurred with Cu resistance gene cutA, acid resistance gene acrP, Cd-Hg-TBT-H₂O₂-HCl resistance gene PA0320 and a phage integrase (XVII).

Some co-occurrences were detected in pigs from both French and Chinese farms. For example, the polymyxin resistance gene pmrF, fosfomycin resistance gene glpT, micronin J25 resistance gene YqjL were found on the same contig with a QACs-H₂O₂ resistance gene kpnO and a Fe resistance gene pmrG (XVIII). When analyzing the data from both farms it could be detected that the genes encoding the two-component regulatory system CpxAR co-occurred with Fe-Zn resistance gene ferF, Se-H₂O₂ resistance gene sodA and Sb-As-glycerol uptake and resistance gene glpF (XIII). Besides, Cu resistance gene cpaA, cueR and Fe-H₂O₂ resistance genes fetA, fetB were frequently detected to co-occur with genes encoding the AcrA/A/B multidrug efflux pump operon in both farms (IV). Furthermore, co-occurrences were also detected in pig farms as follows: acid resistance genes including gadE, hdeA, hdeB, mdtE, mdtF, gadW, gadX, gadA were located in the same contig with Zn-Te resistance gene pitA and As resistance gene arsA/B/R (XII); Betalactam resistance gene pBP3 was found to co-occur with two Cu resistance gene corD, cueO, Fe resistance gene yghL (only in Chinese pigs), one BRG ostA and one transposase gene (XX); A Cd-H₂O₂-HCl resistance gene yhcN co-occurred with the efflux pump system AcrE/F and its repressor AcrS (VI); A broad spectrum MDR ABRG mdfA was detected in the same contig with Cn-nitrofuran resistance gene nfsA (XV).

In this study, we plotted a network to demonstrate the co-occurrences between ARGs and MGEs in the same contigs (Fig. 3B). In total, 282/1261 ARGs were co-located with MGEs on the same contigs, referred to as mobile ARGs. Mobile ARGs were abundant in the pigs from Chinese and Danish farms, especially ARGs co-located with genes encoding transposase. The mobile lincosamide resistance gene linMC was frequently detected in the contigs from all three farms. The mobile cephalosporin resistance genes CfxA2/CfxA6 and penam resistance gene ACI-1 were also abundant in the pigs from Danish and Chinese farms. These tetracycline resistance genes (tetA40)/(42)/(C)/44/W/O/Q/Y/adeF), macrolide resistance genes (ermA/B/F/G/Q) and aminoglycoside resistance genes (ANT(6)-Ia/ANT(6)-Ib/APH(2)-Ila/APH(3)-Ila/APH(6)-IId/aadA/aadA2) were also frequently detected to co-locate with MGEs in the same contigs. The polymyxin resistance gene pmrF was found to be in the vicinity of genes encoding transposases in the same contig. Colistin resistance-related genes mexB and oprM, and polymyxin B resistance gene epiA were also detected to co-occur with MGEs in Chinese and Danish pigs. The detailed information for the network has been summarized in Table S6.

3.4 Mobilizable contigs carrying ARG, BRG/MRG and MGEs are concentrated in Enterobacteriaceae

To investigate which clades of bacteria tended to maintain and spread ARGs in the form of co-selection and also confirm the accuracy of contig assembly, we blasted the contigs carrying ARGs, MGEs, BRGs/MRGs against the NCBI RefSeq database consisting of 138, 683 genomes. All the contigs could be found in reference genomes. After filtering with a very strict threshold, all the successfully mapped taxa were displayed in the tree (Fig. 4). The size of nodes in the tree was proportional to the mapped occurrence of the bacterial taxa. Proteobacteria was the only hit phylum, under which family Enterobacteriaceae displayed the biggest class branch. Notably, the opportunistic pathogen E. coli and the pathogen Shigella flexneri were the most mapped species (Fig. 4).

4. Discussion

The current study provides a comprehensive analysis based on the genetic linkage of bacterial co-occurrence profiles between ARGs and other genetic elements including MRGs, BRGs and MGEs in the gut microbiome of 278 pigs from Danish, French and Chinese farms. The antibiotic feeding mode of pigs in the Chinese, Danish and French farms can stand for an unmonitored mode, European standard mode and organic mode, respectively. Compared to antibiotics, the usage of metals as a growth promoter in pig farming has received little restriction around the world and biocide usage in the pigsty and vegetable feed did so far not cause much attention either.

We found that the extent of antibiotic use seemed to be correlated to the load of mobile ARGs. The gut of pigs in the Chinese farm contained the most abundant mobile ARGs, followed by pigs from Danish farms and lastly the pigs from French farms. Likewise, oral antibiotic treatment enhanced the possibility for MGE-mediated ARG exchange in fish guts (Sàenz et al., 2019). The abundance and type of MRGs and BRGs did not vary a lot among the different farms. MRGs and BRGs were present in the gut of pigs from all farms, particularly genes encoding resistances to Zn, Cu, Ag, Ni, As, Cd, QAC. In general, Cu and Zn are the most common
Fig. 3. The patterns of Co-occurrence in assembled contigs. A) The arrangement of resistance genes within the co-occurrences-carrying representative contigs. Only those co-occurrences present in at least two different contigs are listed. ABRG stands for the gene conveying resistance to antibiotic and biocide; AMRG stands for the gene conveying resistance to antibiotic and metal; BMRG stands for the gene conveying resistance to biocide and metal; ABMRG stands for the gene conveying resistance to antibiotic, biocide and metal. The location and size of genes are proportional to the actual condition; the country flag stands for the location of the farm raising the pigs that have the corresponding co-occurrences and its row order stands for the decreasing co-occurrence frequency. B) Network of co-occurring ARGs and MGEs on the same contigs. For view purposes, only the co-occurrences between ARGs and MGEs which are present in at least 5 different contigs are shown in this network. The size of node, node label and the weight of edge are proportional to the number of co-occurred contigs.
component regulatory systems that mediate co-regulation as well. For around 10.8% (282/1261) ARGs, which co-occurred with MGEs especially genes encoding transposase, had the potential to be transferred via HGT. Some previous work had shown that the levels of transposases are highly correlated to the abundance of ARGs from other environments (Aziz et al., 2010; Zhu et al., 2013). Despite the fact that MGEs are fundamentally self-interested and replicate for their own benefit, they frequently transfer beneficial genes to their hosts and neighbors (Rankin et al., 2010), which contributes directly to bacterial evolution, potentially to bacterial speciation, and to the spread of adaptive and symbiotic traits linked to host survival. In this study, around 10.8% (282/1261) ARGs, which co-occurred with MGEs especially genes encoding transposase, had the potential to be transferred via HGT. Some previous work had shown that the levels of transposases were highly correlated to the abundance of ARGs from other environments (Aziz et al., 2010; Zhu et al., 2013).

In this study, co-selection phenomena were investigated via co-occurrence patterns as a proxy. We found that regardless of antibiotics, a portion of AMR can be maintained by co-occurrence with MGEs/BRGs. Despite little/no antibiotic use in Danish and French farms, cross-resistance, for example, mdtA/B, mdtE/F, mdtN/O, cpxA/R, acrA/B/R, acrE/F, emrA/B/R, emrK/Y, gadA/X/W, baeR/S, soxS/R, which confer multidrug resistance towards antibiotics, biocides and/or metals, can still help to maintain AMR under exposure stress from biocides and/or metals. Of these, some multidrug resistance genes can encode multiple-component regulatory systems that mediate co-regulation as well. For example, the BaeRS two-component regulatory system can activate transcription of many resistance genes (Nishino et al., 2005) such as mdtA/B/C/D transporter gene clusters and acrD (Baranova and Nikaido, 2002; Nagakubo et al., 2002). The CpxAR two-component regulatory system can activate transcription of the multiple antibiotic resistance regulatory operon marA/B/R (Weatherspoon-Griffin et al., 2014). The gene soxS can enhance the expression of the Zn uptake system ZnuACB (Warner and Levy, 2012) and the AcrAB-ToIC multidrug efflux protein complex (Pérez et al., 2012). In addition to cross-resistance, co-resistance phenomena detected in pigs especially from French farms further highlighted the role of metals/biocides on the maintenance and spread of ARGs. These co-resistance patterns were either genetically linked such as in acrA/B/R or probably reflected the historical and current chemical environments (Ye et al., 2017). Zhu et al found that the co-selection of Cu, Zn, tetracycline resistance determinants and MGEs would be favored in exposed microbial communities due to the use of Cu, Zn, and antibiotics such as tetracycline in pig farming (Zhu et al., 2013). Accordingly, we speculate that microbes in the gut of pigs mainly faced the selection pressures from Cu, Ni, Zn, fluoroquinolone, penam, tetracycline, cephalosporin, acid, QACs, acridine since the co-occurrences of them were frequently detected in this study. The pigs raised in the Chinese farm had the most contigs with co-occurrences which probably suggests that continuous selection pressure from antibiotics can probably provide more abundant ARGs as the subsequent subjects for the co-selection by metals and biocides. In summary, antibiotics are not the sole factor for the spread and preservation of ARGs in their ecological environment.

Notably, we found some polymyxin resistance genes and their co-occurrences with other resistance genes. As we know, polymyxins have reemerged as a final line of defense against Gram-negative `superbugs’ (Sun et al., 2018). The co-occurrences of polymyxin resistance genes and other resistance genes would aggravate their spread and maintenance. In this study, although we found class 1 integrons carrying ARG cassette in pigs only from the Chinese farm, the plasmids carrying these integrons have been found around the world (Fig. S2-b/d) and mostly in pathogens. Integron are well-known genetic agents responsible for the capture and dissemination of ARGs (Partridge et al., 2018) particularly among gram-negative clinical isolates (Rowe-Magnus and Mazel, 2002). Most of the known ARG cassettes were captured by class 1
integrins (Mazel, 2006), which substantially contributed to the spread and presence of ARGs among bacterial species. The co-occurrence between QAC resistance genes qacF/qacEΔ1 and ARG cassettes in the integrins could help AMR maintenance in pathogens. Similarly, Gaze et al found that the incidence of class I integrins was significantly higher for bacteria exposure to QACs (Gaze et al., 2005).

Enterobacteriaceae tended to have more ARGs/MRGs/MGEs carrying DNA fragments detected in this study, especially in E. coli and Shigella flexneri. Shigella flexneri can cause a variety of communicable bacterial dysenteries in their hosts (Jennison and Verma, 2004). E. coli carries a high level of ARGs (Li et al., 2021) and acts as a transfer station for ARGs to other bacteria in the gut. The detected abundant co-occurrence between ARGs and BRGS/MRGs may increase the persistence of ARGs in E. coli. The era of plentiful antibiotics is forcing more bacteria to develop ARGs to survive and grow in the newly established toxic environment, while non-degradable metals and easily accessible biocides probably further promote the maintenance and spread of AMR in the form of co-occurrence investigated in this study, which represents an increased public health risk.

While this study can distinguish patterns of co-selection that align with countries and farms that are known to have large differences in antibiotics usage, it is a limitation that there are no observations on many other aspects of farming practices. Cleaning agents and frequency of use could be used to separate the variance of these, but ultimately intervention designs are needed to establish practices that can minimize the horizontal spread of ARGs.

5. Conclusion

In this study, we have used publicly available data to map the mobilizable resistance genes in pig gut microbiomes and exploited the patterns of co-selection by non-antibiotic factors including metals and biocides. The genetic evidence presented here clearly suggests these factors contribute to the maintenance of AMR in pig farming. We demonstrate the commonness of this co-selection with genetic evidence and augment this with an overview of mobilizing elements. We clarify in a One Health approach.
