We report on current-voltage measurements of the zero-field normal-superconducting phase transition in thin films of Pr$_{2-x}$Ce$_x$CuO$_{4-y}$ as a function of doping. We find that the small size of the critical regime in these materials ($\approx 25$ mK) gives rise to mean-field behavior at the phase transition with a static exponent of $\nu \approx 0.5$ for all dopings (in contrast to hole-doped YBa$_2$Cu$_3$O$_{7-\delta}$). We also find mean-field behavior in the dynamic exponent $z$. This indicates that Pr$_{2-x}$Ce$_x$CuO$_{4-y}$ behaves similarly to conventional superconductors in contrast to other cuprate superconductors. However, as the transition width in our samples decreases, the dynamic critical exponent approaches $z = 1.5$, similar to the critical exponent found in hole-doped YBa$_2$Cu$_3$O$_{7-\delta}$.

I. INTRODUCTION

The discovery of high-temperature superconductors led to predictions of an unusually large critical regime as well as new theories describing the superconducting phase transition in field and in zero field. These predictions led to a large number of measurements of the phase transition in the hole-doped cuprate superconductors via: specific heat measurements, thermal expansivity, magnetic susceptibility, and transport.

Recent attention has shifted to the phase transition of the electron-doped superconductors R$_{2-x}$Ce$_x$CuO$_{4-y}$ (R = Nd, Pr, La, Sm). Previous research focused on the quantum critical point thought to occur near optimal doping, but there has been very little research on the more well-established vortex-glass transition and almost none on the second-order normal-superconducting transition in zero field. Earlier work on Nd$_{2-x}$Ce$_x$CuO$_{4-y}$ (NCCO) in a magnetic field reports values for the dynamic and static critical exponents $\nu$ and $\nu$ for the vortex-glass transition similar to other experiments on the hole-doped cuprates, finding $\nu \approx 3, 4$ and $\nu \approx 2, 0.9$. While work in magnetic fields from 1 mT to 1 T finds a range of exponents $\nu \approx 5 - 9$ and $\nu \approx 0.9 - 1.8$. This wide range of results is similar to results on the hole-doped cuprates.

However, the earlier works on the phase transition of NCCO were carried out before our work proposing a more robust determination of the critical parameters that govern the phase transition. We have also recently uncovered several experimental difficulties in making transport measurements on thin films the full extent of which was not understood when these earlier measurements were taken. Most notably, we have shown that the finite thickness of the films, even of “thick” films $(d \geq 3000 \text{ Å})$ obscures the phase transition. We have found that when we account for these effects, the phase transition in hole-doped YBa$_2$Cu$_3$O$_{7-\delta}$ (YBCO) films and crystals yields consistent exponents for both dc and microwave conductivity measurements, $\nu \approx 0.68 \pm 0.07$, as predicted by three-dimensional (3D) XY theory; and $z = 1.5 \pm 0.2$ indicating Model E dynamics.

In this Article we report on the zero field normal-superconducting phase transition of the electron-doped superconductors and present data on the critical regime of Pr$_{2-x}$Ce$_x$CuO$_{4-y}$ (PCCO) thin films (ranging in thickness from $d \approx 2000 \text{ Å}$ to $d \approx 3000 \text{ Å}$) for a variety of different cerium dopings ($x$). We show behavior consistent with a second-order phase transition, however, unlike recent results in YBCO, our results in PCCO are consistent with mean-field theory rather than 3D-XY theory. Moreover, we find that at low currents, the phase transition is obscured by finite size effects, similar to results in YBCO.

II. CRITICAL DYNAMICS IN CUPRATES

To understand some of the differences in the electron-doped and hole-doped cuprates, we must look at the prediction for the size of the critical regime, determined when mean-field theory breaks down:

$$|T - T_{c0}| < \frac{4\pi\mu_o H_{c2}^2(0)}{e^2\Phi_0} k_B T_c^3$$

$$< 4.6 \times 10^{-8} \frac{k^3 T_c^3}{H_{c2}(0)}.$$

(1)

where $e$ is the base of the natural logarithm, $k$ is the ratio of the penetration depth $\lambda$ to the coherence length $\xi$, $T_{c0}$ is the mean-field transition temperature (measured in kelvin), and $\mu_o H_{c2}(0)$ is the GL upper critical field (measured in tesla). $H_{c2}(0)$ is not the experimental critical field, but is the extrapolation from near the critical regime to $T = 0$. For conventional superconductors, $k \approx 10$, $T_{c0} \approx 10$ K, and $\mu_o H_{c2}(0) \approx 1 \text{ T}$. Thus, mean-field theory breaks down only when $|T - T_{c0}| < 1 \mu K$. This makes the critical regime impossible to access experimentally, and the success of mean-field theory in describing the behavior of conventional superconductors is well documented.

FIG. 1: (Color online) Resistivity versus temperature for sev-
eral dopings on \( d \approx 2900 \) Å thick films patterned into 8 \times 8
\( \mu \)m\(^2\) bridges. The inset shows the transition region.

This equation can be modified to fit the anisotropic
cuprate superconductors. In most cuprates, the
\( a \) and \( b \) axes are nearly identical and much smaller than the
\( c \) axis, so we examine the penetration depth along the
\( a \) and \( b \) axes (\( \lambda_{ab} \)) compared to the \( c \)-axis (\( \lambda_c \)), as well
as the coherence length along the different axes (\( \xi_{ab} \) and
\( \xi_c \)). Superconductivity occurs in the \( ab \) planes. Including
anisotropy, Eq. \( 1 \) becomes

\[
|T - T_{c0}| < 4.6 \times 10^{-8} \frac{k^4 T^3}{\gamma^2 H^2_{c2}(0)}.
\]

Here \( \kappa = \lambda_{ab}/\xi_{ab} \) and the anisotropy parameter is \( \gamma = \xi_c/\xi_{ab} \). For YBCO, using \( \kappa = 100 , \mu_a H_{c2}(0) = 300 \) T
\( T_{c0} = 90 \) K, and \( \gamma = 0.2 \), we find \( |T - T_{c0}| < 350 \) mK.
Experimental researchers have found that the critical
region in YBCO can extend far beyond where GL theory
breaks down and can be up to 28 times larger (\( \pm 10 \) K).

The situation is markedly different for PCCO. Not
only is the critical temperature reduced by roughly a
factor of five, the electron-doped cuprates are far more
anisotropic. Using \( \lambda_{ab} = 2000 \) Å, \( \xi_{ab} = 80 \) Å, \( \xi_c = 3.5 \) Å, we
find \( \gamma \approx 0.04 \) and \( \kappa \approx 25 \). With \( \mu_a H_{c2}(0) = 7 \)
T and \( T_{c0} = 20 \) K, we find that \( |T - T_{c0}| < 13 \) mK, more
than ten times smaller than the hole-doped cuprates.
This leads to a critical regime of roughly 25 mK about
\( T_c \). It is not unreasonable to expect that the critical regime
in PCCO will be larger than predicted and may extend
to \( \pm 360 \) mK about \( T_c \), as has been seen in YBCO.

III. SAMPLE GROWTH AND EXPERIMENTAL APPARATUS

The samples for our measurements are grown via
pulsed laser deposition onto SrTiO\(_3\) (100) substrates.

X-ray diffraction verified that our films are \( c \)-axis ori-
entation, and ac susceptibility measurements show that
\( T_c \approx 20 \) K and \( \Delta T_c \lesssim 0.4 \) K for optimal doping, indi-
cating high quality films. Typical samples of thickness
\( d \approx 2900 \) Å are shown in Fig. 1\(^T\) showing \( T_c \approx 21 \) K
and \( \Delta T_c \approx 0.3 \) K at optimal doping (\( T_c \) decreases and
\( \Delta T_c \) increases for under- and over-doped films). These
films are of similar quality as most PCCO films reported
in the literature.

We photolithographically pattern our film into a 4-
probe bridge with dimensions 8 \( \mu \)m \times 80 \( \mu \)m,
etched with a low power ion mill for 30 minutes without
noticeable degradation of \( R(T) \). Contact is made to the
sample leads by depositing a 200 \( \mu \)m thick layer of gold
on contact pads. To ensure we do not change the oxygen
content of the sample, we do not heat the sample during
the gold deposition.

Our cryostat can achieve temperature stability better
than 1 mK at 20 K. To protect that sample from ambient
magnetic fields that could disrupt measurements,\(^12\) our
cryostat is placed in \( \mu \)-metal shields, which reduces the
field at the sample to \( 2 \times 10^{-7} \) T. To reduce noise,\(^13\) we
make all connections to the probe with shielded triax
cable through low-pass \( \pi \)-filters.

IV. DYNAMIC CRITICAL EXPONENT

We have measured the electric field \( E \) vs. the current
density \( J \) (\( E-J \) curves) on 15 samples of different dop-
ings and thicknesses varying from 1920 Å to 3500Å. The
resistivities of four typical samples are shown in Fig. 1.
For every film, we measure the \( E-J \) curves near the
transition temperature. A typical set of data is shown in
Fig. 2(a), taken on the optimally doped film from Fig.
1. In this plot, above \( T_c \) at low currents, we see ohmic
behavior: isotherms with a slope of 1 on a log-log plot
(the dashed line). The isotherm at 21.75 K is almost
fully ohmic. At lower temperatures, high currents show
power-law behavior with isotherms of slope greater than
1, lower currents show ohmic behavior. At the lowest
temperatures, the isotherms show highly non-linear
behavior with slopes approaching infinity, indicating a tran-
sition to the superconducting state. In this figure we can
see clear evidence of a phase transition that occurs over
less than 600 mK.

Scaling analysis of the normal-superconducting phase
transition predicts

\[
E \xi^{2+z-D}/J = \chi_\pm (J \xi^{D-1}/T),
\]

where \( D \) is the dimension, \( z \) is the dynamic critical ex-
ponent, \( \xi \) is the coherence length, and \( \chi_\pm \) are the scaling
functions for above and below the transition tempera-
ture \( T_c \). Fluctuations are expected to have a typical size
\( \xi \) which diverges near \( T_c \) as \( \xi \sim |T/T_c - 1|^{-\nu_c} \), defining a
static critical exponent \( \nu \). The fluctuations are predicted
to have a lifetime \( \tau \) where \( \tau \sim \xi^z \), or \( \tau \sim |T/T_c - 1|^{-\nu z} \).
FIG. 2: (Color online) (a) shows $E - J$ curves of the optimally doped film from Fig. 1 in zero magnetic field (2920 Å thick with bridge dimensions $8 \times 40 \, \mu$m$^2$). Isotherms are separated by 50 mK, and error bars are indicated when larger than the thickness of the lines. The dashed line indicates a slope of 1, or ohmic behavior. Low-current ohmic tails due to finite size effects are obvious for $J \lesssim 10^6$ A/m$^2$. (b) shows the logarithmic derivative of the $E - J$ curves. The high current densities obey the opposite concavity criterion, indicating $T_c = 21.65$ K. From the intercept we determine $z = 1.3 \pm 0.1$.

Exactly at $T_c$, the coherence length diverges while the electric field in the sample remains finite. From Eq. 4 we can see that this is only true if, at $T_c$,

$$E \sim J^{\frac{z+1}{z-1}}.$$  

(4)

We have shown that a logarithmic derivative is a sensitive tool to examine the phase transition and find the critical temperature.\textsuperscript{11,14} From Eq. 4 we know that the critical isotherm will appear as a horizontal line with intercept $(z+1)/2$ on a logarithmic derivative plot (assuming three dimensions). Isotherms above and below the critical isotherm will display opposite concavity about the critical isotherm. The logarithmic derivative of the $E - J$ curves in Fig. 2(a) is shown in Fig. 2(b).

Fig. 2(b) demonstrates results very similar to those reported in YBCO, and displays the behavior predicted to occur in the normal-superconducting phase transition. Isotherms at higher currents ($J > 10^6$ A/m$^2$) show the opposite concavity criterion isotherms above 21.65 K bend down, and isotherms below 21.65 K bend upwards, leading us to identify $T_c = 21.65$ K as the critical temperature.

The most prominent feature of the data in Fig. 2(b) is the peak in the isotherm at 21.60 K. In fact, all power-law isotherms at or below $T_c$ (isotherms with a zero or negative slope on the semi-log plot) eventually switch to ohmic isotherms, limited only by the sensitivity floor of our nanovoltmeter. Power-law isotherms above $T_c$ (isotherms with a positive slope) are expected to become ohmic at low currents, but isotherms below or at $T_c$ are not.

This ohmic behavior at low currents occurs due to finite size effects even in films as thick as 3000 Å.\textsuperscript{14,17} Different applied currents probe fluctuations of different sizes, leading to a minimum current density, such that smaller current densities probe 2D fluctuations:

$$J_{\text{min}} = \frac{ck_BT}{\Phi_o q^2},$$  

(5)

where $\Phi_o = \frac{h}{2e}$, $d$ is the thickness of the film, and $c$ is
a constant expected to be a constant of order one or on the order of the anisotropy parameter $\gamma^\frac{1}{2}$. 

For the 2920 Å film shown in Fig. [2] from Eq. [5], this minimum current density occurs at $J_{\text{min}} \approx 1.7 \times 10^6$ A/m$^2$ (assuming $\gamma = 1$). We can see in Fig. [2]b that this is indeed the current density where the isotherms below $T_c$ bend back towards ohmic behavior. This result indicates that, despite any differences between the hole-doped and the electron-doped cuprates, the normal-superconducting phase transition in both materials is obscured in films due to finite size effects. Conventionally, low-current ohmic tails are used to find the static critical exponent, as $E/J \sim |T/T_c - 1|^z$. Our results indicate that the low-current data in PCCO cannot be used to find the static critical exponent $\nu$ in PCCO.

We can still use these data to find the dynamic critical exponent $z$. This exponent is expected to be universal, but dc conductivity measurements in hole-doped cuprates in zero field have found a wide range of dynamic critical exponent values, with $z$ ranging from 1.25 to 8.3. AC measurements have found both diffuse dynamics ($z = 2$) as well as Model E dynamics ($z = 1.5$). Our recent results in YBCO find $z = 1.5 \pm 0.2$ for both dc and ac conductivity measurements in crystals and films, when we account for finite size effects.

To properly account for finite size effects in dc measurements, we must limit ourselves to the high current regime ($J > 10^6$ A/m$^2$) to determine the dynamic critical exponent $z$. We recognize that the high currents obey the opposite concavity criterion, and we use the horizontal portion of the critical isotherm in Fig. [2]b to determine the intercept (denoted by the dotted line) $\Delta T_c$ [20]. From Eq. [1] this intercept is equal to $(z + 1)/2$, allowing us to solve for the dynamic critical exponent, $z$. For our data, we find $z = 1.3 \pm 0.1$. A similar analysis can be conducted on all of the films of various dopings to find $z$ as a function of doping. These values of $z$ as a function film transition width $\Delta T_c$ are presented in Fig. [3]. In Fig. [3] we find no systematic change in $z$ as a function of doping, and moreover, many of the values for $z$ are smaller than any previous measurements, and several have values of $z \approx 1$, indicating ohmic behavior. Moreover, if $z = 1$, the lifetime of the fluctuations are directly proportional to the size of the fluctuations (recall $\tau \sim \xi^z$). This “ballistic motion” is not predicted by any theory of the phase transition.

In Fig. [3] we see a strong correlation between the transition width $\Delta T_c$ and the dynamic critical exponent. As the transition width decreases, the dynamic exponent tends towards $z = 1.5$ [30]. This is easiest to see in optimally doped films ($x = 0.15$). The transition temperatures of these films are all between 19 K and 21.6 K, changing by only 12%, but the transition widths vary from 0.2 K to 2.55 K, changing by more than a factor of 10. Thus the variations in $z$ are driven by the transition width as opposed to the transition temperature. Moreover, films of different dopings follow a general trend of decreasing dynamic critical exponent as transition width increases (excluding the two outliers) [32], though for highly over- and under-doped films, the transition width is much wider.

From Eq. [1] we predicted the size of the critical regime to be on the order of $\pm 13$ mK and possibly as large as $\pm 360$ mK. This means that samples must be homogeneous with transition widths smaller than 0.72 K in the best case scenario, and smaller than 0.026 K in the worst case scenario. Change in transition widths imply sample inhomogeneity, thus the critical behavior of one part of the sample will be dominated by the larger signal generated by the mean-field behavior of different part of the sample with a slightly different $T_c$, especially as the critical regime is so small in PCCO. This indicates that the critical regime will be obscured in films with the broad transition widths. Our data confirm this hypothesis: At the smallest transition widths, we find $z \approx 1.5$ in optimally-doped and $x = 0.16$ films, similar to results in YBCO [35].

However, as the transition width increases the dynamic critical exponent tends towards $z = 1$. Our results imply that only in more homogeneous films, with transition widths smaller than current transition widths will we be able to unambiguously see critical dynamics for all dopings (though whether all dopings will have the same dynamic critical exponent as optimally-doped PCCO and YBCO is unknown). However, our films are of similar or better quality than most reported in the literature, and recent improvements in PCCO film growth remove impurities but do not decrease the transition widths.

A scaling analysis of these data indicates that $z \approx 1$ for films with broad transition widths, which implies $\tau \sim \xi$ (not predicted by any theories). However, rather than indicating a new type of phase transition, this indicates the failure of scaling analysis to describe the behavior of these films. In a conventional superconductor, there is a rapid change from the normal state with ohmic behavior ($E \sim J$) to the superconducting state, which is highly non-ohmic with $E \sim J^a$, where the power $a$ increases as current density decreases (recall that as $J$ approaches the critical current density, $a \to \infty$). Looking only at the power $a$, for a conventional superconductor above $T_c$, we see that $a = 1$ and is independent of $J$, below $T_c$, $a(J) > 1$. This is precisely the behavior we see in our films with wide transition widths. We identify the transition temperature as the lowest temperature isotherm whose power $a$ (the slope on the logarithmic derivative plot) does not vary with $J$. We then use that slope to calculate $z$, recalling $a = (z + 1)/2$, and if $a = 1$, then $z = 1$. However, this analysis is flawed: what we are seeing is the rapid change (usually in less than 0.1 K) from ohmic behavior ($a = 1$) to non-ohmic behavior ($a > 1$). In this way, the phase transition in PCCO is similar to the phase transition in conventional superconductors (rapid switch from ohmic to non-ohmic behavior), and indicates mean-field behavior rather than critical behavior. This in turn indicates that, in regards to the normal-superconducting phase transition, PCCO usually behaves like a conventional superconductor. Moreover, conducting a scaling analysis on this kind of system to find $z$ is intrinsically
flawed – the dynamic exponent $z$ we measure is not the critical exponent for any phase transition, but rather an indication that the critical dynamics cannot be used for films where the transition width is large compared to the critical regime.

V. STATIC CRITICAL EXPONENT

We have also measured the static critical exponent $\nu$ as a function of doping. Although we cannot use the low-current ohmic tails to measure $\nu$, as is conventionally done, in small magnetic fields, we measure

$$T_c(0) - T_g(H) \sim H^{1/\nu}, \quad (6)$$

where $T_c(0)$ is the zero-field transition temperature, $T_g(H)$ is the vortex-glass transition temperature and $\nu$ is the zero-field static critical exponent. Eq. (6) is valid both for critical dynamics, where 3D-XY predicts $\nu \approx 0.67$, and for mean-field theory, which predicts $\nu = 0.5$. Recent measurements on thin-film YBCO using this method found $\nu = 0.68 \pm 0.05$. A typical measurement is shown in the inset of Fig. 4 which shows the log-log plot of $T_c(0) - T_g(H)$ vs. $H$ for a film of doping $x = 0.14$. The slope of this line can be used to find $\nu$ and its error. The results for all of the films as a function of doping are shown in Fig. 4. The dashed line at the top of the figure is $\nu = 0.67$, the result predicted from 3D-XY theory. The lower dashed line is $\nu = 0.5$, the result predicted from mean field theory. For all dopings, we see that $\nu \approx 0.5$, indicating a mean-field transition. For all dopings, we see that $\nu \approx 0.5$, indicating a mean-field transition.

VI. CONCLUSION

We have shown that PCCO undergoes a second-order phase transition in zero field. The transition obeys the opposite concavity criterion for current densities greater than $10^6$ A/m$^2$, below these current densities, the phase transition is obscured by finite size effects. We predicted the size of the critical regime in PCCO to be $|T - T_0| < 25$ mK, which means that the critical dynamics of these films will be obscured by the large transition width in these materials ($\Delta T_c$ varies from 0.2 K to 2.55 K). This in turn implies that the normal-superconducting phase transition in PCCO will obey mean-field theory, similar to conventional superconductors, as opposed to critical dynamics and 3D-XY theory, as recently seen in YBCO.23 Our measurements of the static critical exponent confirm this hypothesis, as $\nu \approx 0.5$ for PCCO films of all dopings. We also see behavior similar to conventional superconductors in the $E - J$ curves, which show a rapid change from ohmic to non-ohmic behavior. This behavior, if analyzed using scaling analysis, gives an erroneously low value for $z$, $z \approx 1$. However, for optimally-doped films with extremely narrow transition widths, we find that as $\Delta T_c \rightarrow 0$, $z \rightarrow 1.5$. Thus as the transition width decreases, we are able to recover the same dynamic critical exponent found in optimally-doped YBCO.15

20. This equation differs from Lobb’s formula in Ref. [1] by a factor of $4/e^2$ (roughly $\frac{1}{\xi}$). Lobb assumes equipartition for one mode (a real order parameter). We have used equipartition for two modes (a complex order parameter), leading to a factor of 4. Lobb also uses the small-$r$ approximation of the correlation function ($V(r) \sim e^{-r/\xi}/r$) when $V(r) \sim 1/r$. Because we are interested when $r \approx \xi$, we have used $\Gamma(\xi) \sim 1/\xi$, leading to a factor of $1/e^2$.

25. Measurements in Fig. [12] were taken with an applied current density of $J \approx 10^8$ A/m$^2$, thus the resistive transition width are wider than those reported in Fig. [10] by roughly 40% due to finite size effects.

31. The $T_c$ was measured via the opposite concavity criterion and the magnetic susceptibility agree to within the measurement error of the thermometers ($\pm 0.25$ K), indicating that the $T_c$ as measured via the opposite concavity criterion agrees with the bulk measurement of the transition temperature.
32. We calculated $\Delta T_c$ by using the 90% - 10% criterion; i.e., we found the resistivity of lowest-temperature ohmic isotherm from the $E - J$ curves, and then found the temperatures that corresponded to 90% of that resistivity and 10% of that resistivity to calculate $\Delta T_c$. We used the resistivity at $J = 10^8$ A/m$^2$ to avoid finite-size effects. An alternative method of measuring $\Delta T_c$ using magnetic sus-
ceptibility yields similar results (with a smaller scale along the abscissa).

There are two films ($x = 0.14$ and $x = 0.17$) that deviate strongly from the general trend shown in Fig. 3. At this time, we are unsure why these films deviate from the general trend, as growth, processing, and measurement were the same for these films as for all the others presented in Fig. 3. However, we note that other films of the same doping and similar dopings do follow the trend, and so our overall conclusion is still valid.
