Optimal Index Codes with Near-Extreme Rates

Son Hoang Dau, Vitaly Skachek, and Yeow Meng Chee, Senior Member, IEEE

Abstract—The min-rank of a digraph was shown by Bar-Yossef et al. (2006) to represent the length of an optimal scalar linear solution of the corresponding instance of the Index Coding with Side Information (ICSI) problem. In this work, the graphs and digraphs of near-extreme min-ranks are characterized. Those graphs and digraphs correspond to the ICSI instances having near-extreme transmission rates when using optimal scalar linear index codes. In particular, it is shown that the decision problem whether a digraph has min-rank two is NP-complete. By contrast, the same question for graphs can be answered in polynomial time.

Additionally, a new upper bound on the min-rank of a digraph, the circuit-packing bound, is presented. This bound is often tighter than the previously known bounds. By employing this new bound, we present several families of digraphs whose min-ranks can be found in polynomial time.

I. INTRODUCTION

Building communication schemes which allow participants to communicate efficiently has always been a challenging yet intriguing problem for information theorists. Index Coding with Side Information (ICSI) ([1], [2]) is a communication scheme dealing with broadcast channels in which receivers have prior side information about the messages to be transmitted. By using coding and exploiting the knowledge about the side information, the sender may significantly reduce the number of required transmissions compared with the straightforward approach. As a consequence, the efficiency of communication over this type of broadcast channels could be dramatically improved. Apart from being a special case of the well-known (non-multicast) Network Coding problem ([3], [4]), the ICSI problem has also found various potential applications on its own, such as audio- and video-on-demand, daily newspaper delivery, data pushing, and opportunistic applications on its own, such as audio- and video-on-demand.

In the work of Bar-Yossef et al. [5], the optimal transmission rate of scalar linear index codes for an ICSI instance was neatly characterized by the so-called min-rank of the side information digraph (i.e., directed graph, see Section II for definitions) corresponding to that instance. The concept of min-rank of a graph (i.e., undirected graph, see Section II for definitions) goes back to Haemers [9]. Min-rank serves as an upper bound for the celebrated Shannon capacity of a graph [10]. This upper bound, as pointed out by Haemers, although is usually not as good as the Lovász bound [11], is sometimes tighter and easier to compute. It was shown by Peeters [12] that computing the min-rank of a general graph (that is, the Min-Rank problem) is a hard task. More specifically, Peeters showed that deciding whether the min-rank of a graph is smaller than or equal to three is an NP-complete problem.

The work of Bar-Yossef et al. [5] has stimulated the interest in the Min-Rank problem. Exact and heuristic algorithms for finding min-ranks over the binary field of digraphs were developed in the work of Chaudhry and Sprintson [13]. The min-ranks of random digraphs are investigated by Haviv and Langberg [14]. A dynamic programming approach was proposed by Berliner and Langberg [15] to compute min-ranks of outerplanar graphs in polynomial time. Algorithms to approximate min-ranks of graphs with bounded min-ranks were studied by Chlamtac and Haviv [16].

In this paper, we study graphs and digraphs that have near-extreme min-ranks. In other words, we study ICSI instances with $n$ receivers for which optimal scalar linear index codes have transmission rates $2, n-2, n-1, \text{or } n$. In particular, we show that deciding whether a digraph has min-rank two over the binary field is an NP-complete problem. In contrast, a graph has min-rank two over any finite field if and only if it is not a complete graph and its complement is bipartite, a condition which can be verified in polynomial time (see, for instance, West [17, p. 495]). Very recently, it was found by Maleki et al. [18] that the same problem for digraph over sufficiently large field can be solved in polynomial time.

The characterization of graphs and digraphs with near-extreme min-ranks are summarized in the table below. The star mark “*” indicates that the result is established in this paper. The dagger mark “†” indicates that the result is proved only for the binary field.

| Min-Rank $n$ | Graph $G$ | Digraph $D$ |
|-------------|------------|-------------|
| 1           | $G$ is complete (trivial) | $D$ is complete (trivial) |
| 2           | $G$ is not complete and $\overline{G}$ is 2-colorable [12] | $D$ is not complete and $\overline{D}$ is fairly 3-colorable$^\dagger$ |
| $n-2$       | $G$ (connected) has a maximum matching of size two and does not contain $P_4$ (Fig. 6) as a subgraph$^*$ | unknown |
| $n-1$       | $G$ (connected) is a star graph$^*$ | unknown |
| $n$         | $G$ has no edges (trivial) | $D$ has no circuits$^\dagger$ |

The near-extreme cases are of significant interest from both theoretical and practical points of view. It is known that the Min-Rank Problem is NP-hard [12] ($\text{minrk}_n(G) = 3$ is hard to verify). Theoretically, it is desirable to further understand,
which values of the min-rank in the range between 1 and \( n \)
are still easy to verify, and for which values it is hard. It turns out that for graphs and digraphs, the easy-hard turning points
are different. For graphs, the turning points are 3 and some value smaller than \( n - 2 \) (not exactly known). By contrast, for
digraphs, the easy-hard turning points are 2 (proved in this work)
and \( n - 1 \) (conjectured). Practically, the use of length-
one index codes in wireless communications has already been
proposed (for instance, see COPE \([7, 19, 20]\)), due to their
simplicity and efficiency. However, the variety of scenarios
where an index code of length one is applicable is limited
(each client must know all except one message). An index
code of length two is obviously the next potential candidate
to be used.

In this paper, we also introduce a new upper bound for
the min-rank of a digraph, namely the circuit-packing bound,
which, in certain cases, is far tighter than the clique-cover
bound. This upper bound was first presented by Chaudhry et al.
\([21]\), and was found independently by the authors of this
paper approximately at the same time.

So far, families of graphs and digraphs whose min-ranks
are either known or computable in polynomial time are the
followings. For graphs, they are odd holes and odd anti-
holes \([22]\), perfect graphs \([23]\), and outerplanar graphs \([15]\).
For digraphs, they are acyclic digraphs \([22]\). In this work,
we point out several new families of digraphs for which the
circuit-packing bound is tight. For such families of digraphs,
min-ranks can be found in polynomial time.

In the context of index coding, we only study min-ranks
of digraphs over a finite field \( \mathbb{F}_q \). However, all of our results,
except Theorem \([IV.7]\) Corollary \([IV.8]\) and Theorem \([V.2]\)
still hold for an arbitrary field \( \mathbb{F} \). This is because the characteristic
of the field does not play any role in their proofs.

The paper is organized as follows. Basic notation and
definitions are presented in Section \([II]\). The ICSI problem
is formulated in Section \([III]\). Section \([IV]\) is devoted to the
characterizations of graphs and digraphs of near-extreme min-
ranks. We prove the hardness of the Min-Rank problem for
digraphs in Section \([V]\). The circuit-packing bound is established
in Section \([VI]\). Finally, some interesting open problems
are proposed in Section \([VII]\).

\section{Notation and Definitions}

Let \([n]\) denote the set of integers \([1, 2, \ldots, n]\). Let \( \mathbb{F}_q \)
denote the finite field of \( q \) elements and \( \mathbb{F}_q^* = \mathbb{F}_q \setminus \{0\} \).
The support of a vector \( u \in \mathbb{F}_q^n \) is defined to be the set
\( \text{supp}(u) = \{i \in [n] : u_i \neq 0\} \). For an \( n \times k \) matrix \( M \),
let \( M_i \) denote the \( i \)-th row of \( M \). For a set \( E \subseteq [n] \), let \( M_E \)
denote the \( |E| \times k \) sub-matrix of \( M \) formed by rows of \( M \)
which are indexed by the elements of \( E \). For any matrix \( M \)
over \( \mathbb{F}_q \), we denote by \( \text{rank}_q(M) \) the rank of \( M \) over \( \mathbb{F}_q \) (or
the \( q \)-rank of \( M \)). We use \( e_i \) to denote the unit vector, which
has a one at the \( i \)-th position, and zeros elsewhere.

A simple graph \( G = (V(G), E(G)) \) where \( V(G) \)
is the set of vertices of \( G \) and \( E(G) \) is a set of unordered pairs
of distinct vertices of \( G \). We refer to \( E(G) \) as the set of edges of
\( G \). A typical edge of \( G \) is of the form \( \{u, v\} \) where \( u \in V(G), v \in V(G) \),
and \( u \neq v \). If \( e = \{u, v\} \in E(G) \) we say that \( u \) and \( v \) are adjacent. We also refer to \( u \) and \( v \) as the endpoints of \( e \).

A simple digraph is a pair \( D = (V(D), E(D)) \) where \( V(D) \)
is the set of vertices of \( D \), and \( E(D) \) is a set of ordered pairs
of distinct vertices of \( D \). We refer to \( E(D) \) as the set of arcs
(or directed edges) of \( D \). A typical arc of \( D \) is of the form \( e = (u, v) \) where \( u \in V(D), v \in V(D), \) and \( u \neq v \).
The vertices \( u \) and \( v \) are called the endpoints of the arc \( e \).

Simple graphs and digraphs have no loops and no parallel
edges and arcs, respectively. In the scope of this paper, only
simple graphs and digraphs are considered. Therefore, we
simply refer to them as graphs and digraphs for succinctness.

The number of vertices \(|V(D)|\) is called the order of \( D \),
whereas the number of arcs \(|E(D)|\) is called the size of \( D \).
The complement of a digraph \( D \), denoted by \( \overline{D} \), is defined as
follows. The vertex set is \( V(\overline{D}) = V(D) \). The arc set is
\( E(\overline{D}) = \{(u, v) : u, v \in V(D), u \neq v, (u, v) \notin E(D)\} \).

Analogous concepts are also defined for graphs.

A digraph \( D \) is called symmetric if it satisfies the property
that \((u, v) \in E(D)\) if and only if \((v, u) \in E(D)\). A symmetric
digraph can be viewed as a graph, and vice versa. A complete
graph is a graph that contains all possible edges. A complete
digraph is a digraph that contains all possible arcs.

A collection of subsets \( V_1, V_2, \ldots, V_k \) of a set \( V \) is said to
partition \( V \) if \( \bigcup_{i=1}^{k} V_i = V \) and \( V_i \cap V_j = \emptyset \) for all
\( i \neq j \). In that case, \( [V_1, V_2, \ldots, V_k] \) is referred to as a partition of \( V \),
and \( V_i \)’s (\( i \in [k] \)) are called parts of the partition.

A graph \( G \) is called bipartite if \( V(G) \) can be partitioned into
two subsets \( U \) and \( V \) such that for every edge \( \{u, v\} \in E(G) \),
it holds that \( u \in U \) and \( v \in V \), or vice versa.

A subgraph of a graph \( G \) is a graph whose vertex set \( V \)
is a subset of that of \( G \) and whose edge set is a subset of that of \( G \)
restricted to the vertices in \( V \). Let \( V \) be a subset of vertices
in \( V(G) \). The subgraph of \( G \) induced by \( V \) is a graph
whose vertex set is \( V \), and edge set is \( \{\{u, v\} : u \in V, v \in V, \{u, v\} \in E(G)\} \). We refer to such a graph as an induced
subgraph of \( G \). A subgraph and induced subgraph of a digraph
can be defined in a similar manner.

A path in a graph \( G \) is a sequence of distinct vertices
\( (v_1, v_2, \ldots, v_r) \), such that \( \{v_s, v_{s+1}\} \in E(G) \) for all \( s \in [r-1] \).
A directed path in a digraph \( D \) is a sequence of distinct
vertices \( (v_1, v_2, \ldots, v_r) \), such that \( \{v_s, v_{s+1}\} \in E(D) \), for all \( s \in [r-1] \).

A circuit in a digraph \( D \) is a sequence of pairwise distinct
vertices \( C = (v_1, v_2, \ldots, v_r) \), where \( \{v_s, v_{s+1}\} \in E(D) \) for all \( s \in [r-1] \) and \( (v_r, v_1) \in E(D) \) as well. A digraph is called acyclic if it contains no
circuits.

A graph is called connected if there is a path from each
vertex in the graph to every other vertex. The connected
components of a graph are its maximal connected subgraphs.
Similarly, a digraph is called strongly connected if there is
a directed path from each vertex in the graph to every other
vertex. The strongly connected components of a digraph are its maximal strongly connected subgraphs.

If $(u, v)$ is an arc in a digraph $D$, then $v$ is called an out-neighbor of $u$ in $D$. The set of out-neighbors of a vertex $u$ in a digraph $D$ is denoted by $N^D_+(u)$. We simply use $N(u)$ whenever there is no potential confusion. We also denote by $N^G(u)$ the set of neighbors of $u$ in a graph $G$, namely, the set of vertices adjacent to $u$ in $G$.

An independent set in a graph $G$ is a set of vertices of $G$ with no edges connecting any two of them. An independent set in $G$ of largest cardinality is called a maximum independent set in $G$. The cardinality of such a maximum independent set is referred to as the independence number of $G$, denoted by $\alpha(G)$. We also use $\alpha(D)$ to denote the size of a maximum acyclic induced subgraph of a digraph $D$ for the following reason. For a symmetric digraph $D$, $\alpha(D)$ is equal to the size of a maximum independent set if $D$ is regarded as a graph.

A clique of a graph is a set of vertices that induces a complete subgraph of that graph. A clique cover of a graph is a clique cover with the minimum number of cliques. The number of cliques in such a minimum clique cover is called the clique cover number of that graph. Similar concepts are defined for digraphs. We denote by $cc(G)$ the clique cover number of a graph $G$ and $cc(D)$ the clique cover number of a digraph $D$.

### III. THE INDEX CODING WITH SIDE INFORMATION PROBLEM

The ICSI problem is formulated as follows. Suppose a sender $S$ wants to send a vector $x = (x_1, x_2, \ldots, x_n)$, where $x_i \in \mathbb{F}_q$ for all $i \in [n]$, to $n$ receivers $R_1, R_2, \ldots, R_n$. Each $R_i$ possesses some prior side information, consisting of the blocks $x_j, j \in \mathcal{X}_i \subseteq [n]$, and is interested in receiving a single block $x_i$. The sender $S$ broadcasts a codeword $\mathcal{C}(x) \in \mathbb{F}_q^t$, where $\kappa$ is some positive integer, that enables each receiver $R_i$ to recover $x_i$ based on its side information. Such a mapping $\mathcal{C} : \mathbb{F}_q^t \rightarrow \mathbb{F}_q^\kappa$ is called an index code. We refer to $t$ as the block length and $\kappa$ as the length of the index code. The ratio $\kappa/t$ is called the transmission rate of the index code. The objective of $S$ is to find an optimal index code, that is, an index code which has the minimum transmission rate. The index code is called linear if $\mathcal{C}$ is a linear mapping, and nonlinear otherwise. The index code is called scalar if $t = 1$ and vector if $t > 1$. The length and the transmission rate of a scalar index code $(t = 1)$ are identical.

**Example III.1.** Consider the following ICSI instance (Fig. 1). There are five receivers ($n = 5$). We only consider scalar index codes in this example. Suppose that $x_i \in \mathbb{F}_2, i \in [5]$, are five messages available from $S$. For each $i \in [5]$, the receiver $R_i$ requests $x_i$ and owns certain messages as a priori. We have here $\mathcal{X}_1 = \{2\}, \mathcal{X}_2 = \{3\}, \mathcal{X}_3 = \{1, 4\}, \mathcal{X}_4 = \{5\}$, and $\mathcal{X}_5 = \{2, 4\}$. 

**Fig. 1:** Example of an ICSI instance

On the one hand, $S$ can satisfy the demands from all receivers simultaneously in a straightforward way by broadcasting all five messages $x_i$’s, $i \in [5]$. This naïve solution costs five transmissions. On the other hand, a smarter solution for $S$ is to broadcast three packets $x_1 + x_2, x_2 + x_3,$ and $x_4 + x_5$. This index code is of length three. The decoding process goes as follows. Since $R_1$ already knows $x_2$, it obtains $x_1$ by adding $x_2$ to the first packet $x_1 + x_2$:  

$$x_1 = x_2 + (x_1 + x_2).$$

Similarly, $R_2$ obtains $x_3 = x_2 + x_3 + (x_2 + x_3)$; $R_3$ obtains $x_3 = x_1 + (x_1 + x_2) + (x_2 + x_3)$; $R_4$ obtains $x_4 = x_5 + (x_4 + x_5)$; $R_5$ obtains $x_5 = x_4 + (x_4 + x_5)$.

Each instance of the ICSI problem can be described by the so-called side information digraph $[5]$. Given $n$ and $\mathcal{X}_i, i \in [n]$, the side information digraph $D = (\mathcal{V}(G), E(D))$ is defined as follows. The vertex set $\mathcal{V}(D) = \{u_1, u_2, \ldots, u_n\}$. The edge set $E(D) = \bigcup_{i \in [n]} \{(u_i, u_j) : j \in \mathcal{X}_i\}$. Sometimes we simply take $\mathcal{V}(D) = [n]$ and $E(D) = \bigcup_{i \in [n]} \{(i, j) : j \in \mathcal{X}_i\}$. If $D$ is a symmetric digraph, we can regard $D$ as a graph, and refer to $D$ as the side information graph.

The side information digraph that describes the ICSI instance in Example III.1 is depicted in Fig. 2. Here we choose $\mathcal{V}(D) = [5]$.

**Fig. 2:** The corresponding side information digraph (Fig 1)

**Definition III.2 ([5]).** Let $D = (\mathcal{V}(D), E(D))$ be a digraph of order $n$, where $\mathcal{V}(D) = \{u_1, u_2, \ldots, u_n\}$.

1. A matrix $M = (m_{ui,u_j}) \in \mathbb{F}_q^{m \times n}$ (whose rows and columns are labeled by the elements of $\mathcal{V}(D)$) is said to fit $D$ if

$$m_{ui,u_j} \neq 0, \quad i = j,$$

$$m_{ui,u_j} = 0, \quad i \neq j, \quad (u_i, u_j) \notin E(D).$$
2) The min-rank of $D$ over $\mathbb{F}_q$ is defined to be \( \text{minrk}_q(D) := \min \{ \text{rank}_q(M) : M \in \mathbb{F}_q^{n \times n} \text{ and } M \text{ fits } D \} \).

Since a graph can be viewed as a symmetric digraph, the above definitions also apply to a graph.

For instance, the two matrices in Fig. 3 fit the digraph $D$ depicted in Fig. 2. The matrix $M_2$ has 2-rank three. By Definition III.2, $\text{minrk}_2(D) \leq 3$. By Theorem III.4 stated below, as $\alpha(D) = 3$, we deduce that $\text{minrk}_2(D) \geq 3$. Thus, $\text{minrk}_2(D) = 3$ and $M_2$ achieves the min-rank.

\[
M_1 = \begin{pmatrix}
1 & 1 & 0 & 0 & 0 \\
0 & 1 & 1 & 0 & 0 \\
0 & 0 & 1 & 1 & 0 \\
0 & 0 & 0 & 1 & 1 \\
0 & 1 & 0 & 0 & 1
\end{pmatrix} \quad M_2 = \begin{pmatrix}
1 & 1 & 0 & 0 & 0 \\
0 & 1 & 1 & 0 & 0 \\
1 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 1 & 1 \\
0 & 0 & 0 & 1 & 1
\end{pmatrix}
\]

(a) A matrix of 2-rank four (b) A matrix of 2-rank three

Fig. 3: Two matrices that fit $D$ (Fig. 2).

Observe that the index code presented in Example III.1 is obtained by taking the dot products of $x$ with the first, the second, and the forth rows of $M_2$. These three rows actually span the row space of $M_2$. This index code has length three, which equals $\text{rank}_2(M_2)$. According to Theorem III.3, this index code is an optimal scalar linear index code over $\mathbb{F}_2$ for the ICSI instance described in Example III.1.

**Theorem III.3** ([5], [23]). The length of an optimal scalar linear index code over $\mathbb{F}_q$ for the ICSI instance described by $D$ is $\text{minrk}_q(D)$.

Let $\beta_q(t, D)$ denote the length of an optimal vector index code of block length $t$ over $\mathbb{F}_q$ for an ICSI instance described by a digraph $D$. Note that we do not require the index codes to be linear. Alon et al. [24] defined the broadcast rate $\beta_q(D)$ of the corresponding ICSI instance to be $\lim_{t \to \infty} \beta_q(t, D)/t$ (see also Blasiak et al. [25] 1). In words, the broadcast rate is the average minimum communication cost per symbol in each block $x_i$ (for long blocks). The reciprocal of $\beta_q(D)$ is also referred to as the capacity (over $\mathbb{F}_q$) of the ICSI instance described by $D$ (see Langberg and Sprintson [26]).

Theorem III.4 ([9], [5], [22], [24]). For any digraph $D$ we have

\[
\alpha(D) \leq \beta_q(D) \leq \beta_q(1, D) \leq \text{minrk}_q(D) \leq \text{cc}(D).
\]

The same inequalities hold for graphs.

**IV. DIGRAPHS OF NEAR-EXTREME MIN-RANKS**

Some of the results presented below are folklore. However, we include their proofs for completeness.

**A. (Strongly) Connected Components and Min-Ranks**

**Lemma IV.1** (Folklore). Let $G = (V(G), E(G))$ be a graph.

Suppose that $G_1, G_2, \ldots, G_k$ are subgraphs of $G$ that satisfy the following conditions

1) The sets $V(G_i), i \in [k]$, partition $V(G)$;
2) There is no edge of the form $(u, v)$ where $u \in V(G_i)$ and $v \in V(G_j)$ for $i \neq j$.

Then

\[
\text{minrk}_q(G) = \sum_{i=1}^{k} \text{minrk}_q(G_i).
\]

In particular, the above equality holds if $G_1, G_2, \ldots, G_k$ are all connected components of $G$.

**Proof:** The proof follows directly from the fact that a matrix fits $G$ if and only if it is a block diagonal matrix (re-labeling the vertices if necessary) and the block sub-matrices fit the corresponding subgraphs $G_i$’s, $i \in [k]$. \qed

**Lemma IV.2** (Folklore). Let $D = (V(D), E(D))$ be a digraph.

If $D_1, D_2, \ldots, D_k$ are all strongly connected components of $D$, then

\[
\text{minrk}_q(D) = \sum_{i=1}^{k} \text{minrk}_q(D_i).
\]

**Proof:** Suppose that $V_i$ is the set of vertices that induces $D_i, i \in [k]$. Then $\{V_i\}_{i \in [k]}$ forms a partition of $V(D)$. By relabeling the vertices of $D$ if necessary, we may assume without loss of generality that for every $i < j$

1) $u < v$ whenever $u \in V_i$ and $v \in V_j$;
2) There are no arcs of the form $(u, v)$ where $u \in V_i$ and $v \in V_j$.

If $M^{(i)}$ is a minimum-rank matrix that fits $D_i (i \in [k])$ then the diagonal block matrix $M$ whose diagonal blocks are $M^{(i)}$ clearly fits $D$. Moreover,

\[
\text{rank}_q(M) = \sum_{i=1}^{k} \text{rank}_q(M^{(i)}) = \sum_{i=1}^{k} \text{minrk}_q(D_i).
\]

Hence $\text{minrk}_q(D) \leq \sum_{i=1}^{k} \text{minrk}_q(D_i)$. It remains to show that $\text{minrk}_q(D) \geq \sum_{i=1}^{k} \text{minrk}_q(D_i)$. Suppose that the matrix $M$ fits $D$. By the assumptions on $V_i$’s ($i \in [k]$) stated at the beginning of the proof, $M$ must be an upper-triangular block matrix, as shown in Fig. 4. If we let $M^{(i)}$ be the sub-matrix of $M$ formed by the rows and columns indexed by the elements of $V_i$, then $M^{(i)}$ fits $D_i$ and hence,

\[
\text{rank}_q(M) \geq \sum_{i=1}^{k} \text{rank}_q(M^{(i)}) \geq \sum_{i=1}^{k} \text{minrk}_q(D_i).
\]

1In [24] and [25], the authors only consider the case $q = 2$, and therefore they use the notations $\beta_2$ and $\beta$, which is independent of the field size. In our notations, this will correspond to $\beta_2(t, D)$ and $\beta_2(D)$. At the moment, it is not clear whether the field size $q$ plays any significant role with respect to the value of $\beta_2$. For example, in this work, the analysis of min-rank for the cases $q = 2$ and $q > 2$ is different (thus, the result in Section IV.C only applies to $q = 2$). Therefore, in the sequel we use the subscript $q$ to ensure the consistency of the notation throughout the work.
digraph. The same statement holds for a graph. 

Proposition IV.3 (Folklore). Let $D = (\mathcal{V}(D), \mathcal{E}(D))$ be a digraph. Then $\minrk_q(D) = 1$ if and only if $D$ is a complete digraph. The same statement holds for a graph.

Proof: Suppose $D$ is a digraph of order $n$. If $\minrk_q(D) = 1$, by the definition of min-rank there exists an $n \times n$ matrix $M = (m_{u,v})$ of $q$-rank one that fits $D$. Then the rows of $M$ must be scalar multiples of each other. Moreover, $m_{u,u} \neq 0$ for all $u \in \mathcal{V}(D)$. Hence $m_{u,v} \neq 0$ for all $u \in \mathcal{V}(D)$ and all $v \in \mathcal{V}(D)$. Therefore, $(u, v) \in \mathcal{E}(D)$ for all $u \neq v, u \in \mathcal{V}(D)$ and $v \in \mathcal{V}(D)$. In other words, $D$ is a complete digraph.

Conversely, suppose that $D$ is a complete digraph. Then $J$, the $n \times n$ all-one matrix, fits $D$ and $\minrk_q(J) = 1$, which implies that $\minrk_q(D) = 1$. The same arguments hold for graphs.

Corollary IV.4. Let $D = (\mathcal{V}(D), \mathcal{E}(D))$ be a digraph. Then $\beta_q(D) = 1$ if and only if $D$ is a complete digraph. The same statement holds for a graph.

Proof: Suppose $\beta_q(D) = 1$. Then by Theorem III.4 $\alpha(D) = 1$. Therefore, $D$ is a complete digraph. Conversely, if $D$ is a complete digraph then by Proposition IV.3 $\minrk_q(D) = 1$. Again by Theorem III.4 $\beta_q(D) = 1$. 

C. Digraphs of Min-Rank Two

In this section, only the binary alphabet is considered. We first introduce the following concept of a fair coloring of a digraph. Recall that a $k$-coloring of a graph $G = (\mathcal{V}(G), \mathcal{E}(G))$ is a mapping $\phi : \mathcal{V}(G) \to [k]$ which satisfies the condition that $\phi(u) \neq \phi(v)$ whenever $(u, v) \in \mathcal{E}(G)$. We often refer to $\phi(u)$ as the color of $u$. If there exists a $k$-coloring of $G$, then we say that $G$ is $k$-colorable.

Definition IV.5. Let $D = (\mathcal{V}(D), \mathcal{E}(D))$ be a digraph. A fair $k$-coloring of $D$ is a mapping $\phi : \mathcal{V}(D) \to [k]$ that satisfies the following conditions:

(C1) If $(u, v) \in \mathcal{E}(D)$ then $\phi(u) \neq \phi(v)$;
(C2) For each vertex $u$ of $D$, it holds that $\phi(v) = \phi(\omega)$ for all out-neighbors $v$ and $\omega$ of $u$.

If there exists a fair $k$-coloring of $D$, we say that we can color $D$ fairly by $k$ colors, or, $D$ is fairly $k$-colorable.

We refer to the condition (C2) as the fairness of the coloring, since this condition guarantees that all out-neighbors of each vertex share the same color.

Lemma IV.6. A digraph $D = (\mathcal{V}(D), \mathcal{E}(D))$ is fairly $3$-colorable if and only if there exists a partition of $\mathcal{V}(D)$ into three subsets $A$, $B$, and $C$ that satisfy the following conditions:

1) For every $u \in A$: either $N_D(u) \subseteq B$ or $N_D(u) \subseteq C$;
2) For every $u \in B$: either $N_D(u) \subseteq A$ or $N_D(u) \subseteq C$;
3) For every $u \in C$: either $N_D(u) \subseteq A$ or $N_D(u) \subseteq B$.

Proof: If $D$ is fairly $3$-colorable, let $A$, $B$, and $C$ respectively be the sets of vertices of $D$ that share the same color. Then clearly $A$, $B$, and $C$ partition $\mathcal{V}(D)$. Moreover, since all out-neighbors of each vertex must have the same color, the three conditions above are obviously satisfied. Conversely, if those conditions are satisfied, then $\phi : \mathcal{V}(D) \to [3]$, defined by

$$\phi(u) = \begin{cases} 1, & u \in A \\ 2, & u \in B \\ 3, & u \in C \end{cases}$$

is a fair $3$-coloring of $D$.

Theorem IV.7. Let $D = (\mathcal{V}(D), \mathcal{E}(D))$ be a digraph. Then $\minrk_3(D) \leq 2$ if and only if $\overline{D}$, the complement of $D$, is fairly $3$-colorable.

Proof: The ONLY IF direction:

By the definition of min-rank, $\minrk_3(D) \leq 2$ implies the existence of an $n \times n$ binary matrix $M$ of $2$-rank at most two that fits $D$. There must be some two rows of $M$ that span its entire row space. Without loss of generality, suppose that they are the first two rows of $M$, namely, $M_1$ and $M_2$ (these two rows might be linearly dependent if $\minrk_2(D) < 2$). Let $A$, $B$, and $C$ be disjoint subsets of $\mathcal{V}(D)$ such that

$$\text{supp}(M_1) = A \cup B, \text{ supp}(M_2) = B \cup C.$$ 

Hence,

$$\text{supp}(M_1) \cap \text{supp}(M_2) = B.$$ 

Since the binary alphabet is considered and the matrix $M$ has no zero rows, for every $u \in \mathcal{V}(D)$, one of the following must
Therefore, vectors whose supports are

In other words, for every

Suppose now that

The IF direction:

Hence for every

Corollary IV.8. A digraph

D has min-rank two over \( \mathbb{F}_2 \) if and only if \( \overline{D} \) is fairly 3-colorable and \( D \) is not a complete digraph.

For a graph \( G \), it was proved by Blasiak et al. \[25\] that \( \beta_2(G) = 2 \) if and only if \( \overline{G} \) is bipartite and \( G \) is not a complete graph. A characterization of digraphs \( D \) with \( \beta_2(D) = 2 \) was also obtained therein. More specifically, it was shown that \( \beta_2(D) = 2 \) if and only if \( D \) does not contain a subgraph isomorphic to an almost alternating cycle. The almost alternating \((2m + 1)\)-cycle \((m \geq 1)\) is defined as follows. Its vertex set consists of all integers between \(-m \) and \( m \), inclusive, and there is an edge from \( i \) to \( j \) if and only if \( j - i \in \{m, m + 1\} \). Based on this characterization, a polynomial time algorithm to recognize a digraph \( D \) with \( \beta_2(D) = 2 \) was also derived in \[25\]. Hence, the question whether an optimal vector nonlinear index code of length two exists for an ICSI instance described by a digraph can be answered in polynomial time. For scalar linear index code, the same question turns out to be hard. We prove later in Section \[V\] that the decision problem whether \( \text{minrk}_2(D) = 2 \) is NP-complete.

D. Digraphs of Min-Ranks Equal to Their Orders

To tackle graphs of min-ranks almost equal to their orders (Section \[IV-D \] \[IV-E \] \[IV-F \]), we employ the concept of maximum matching from graph theory.

Definition IV.9. A matching in a graph is a set of edges without common vertices. A maximum matching is a matching that contains the largest possible number of edges. The number of edges in a maximum matching in \( G \) is denoted by \( \text{mm}(G) \).

The following upper bound on min-rank, so-called the maximum-matching bound, is a weakened version of the clique-covering bound (see Theorem \[III.4 \]).

Proposition IV.10 (Maximum-matching bound). For any graph \( G \) of order \( n \), it holds that \( \text{minrk}_q(G) \leq n - \text{mm}(G) \).

Proof: As the set of vertices of \( G \) can be covered by \( \text{mm}(G) \) cliques of size two (the edges in a maximum matching) and \( n - 2\text{mm}(G) \) cliques of size one (the remaining vertices that are not covered by the edges in the matching), by Theorem \[III.4 \] the proof follows.

Graphs \( G \) that satisfy \( \alpha(G) = n - \text{mm}(G) \) are called Koenig-Egervary graphs \[27\]. It was proved therein that there is a polynomial time algorithm to recognize a Koenig-Egervary graph \( G \) and subsequently find \( \text{mm}(G) \). By Theorem \[III.4 \] and Proposition \[IV.10 \] if \( G \) is a Koenig-Egervary graph then \( \text{minrk}_q(G) = n - \text{mm}(G) \). Moreover, \( \text{minrk}_q(G) \) can be found in polynomial time. The graphs that satisfy the conditions stated in Proposition \[IV.11 \] Proposition \[IV.17 \] and Theorem \[IV.19 \] are all Koenig-Egervary graphs (see their proofs).

Proposition IV.11 (Folklore). Let \( G \) be a graph of order \( n \). Then \( \text{minrk}_q(G) = n \) if and only if \( \text{mm}(G) = 0 \) (or equivalently, \( G \) has no edges).

Proof: If \( G \) has no edges, a matrix fits \( G \) if and only if it is a diagonal matrix, whose entries on the main diagonal are all nonzero. The \( q \)-rank of such a matrix is \( n \). Therefore, \( \text{minrk}_q(G) = n \).

Suppose for contradiction that \( \text{minrk}_q(G) = n \) and \( G \) contains some edge. Then \( \text{mm}(G) \geq 1 \) and we have \( \text{minrk}_q(G) \leq n - 1 \), according to the maximum-matching bound. We obtain a contradiction.
Proposition IV.12. Let $D$ be a digraph of order $n$. Then \( \minrk_q(D) = n \) if and only if $D$ is acyclic.

**Proof:** Equivalently, we show that \( \minrk_q(D) \leq n - 1 \) if and only if $D$ has a circuit.

Suppose that $D$ has a circuit. Then by the circuit-packing bound established in Section VI-A we deduce that \( \minrk_q(D) \leq n - 1 \).

Conversely, suppose that \( \minrk_q(D) \leq n - 1 \). Then there exists a matrix $M$ fitting $D$ whose rows are linearly dependent. In other words, \( \sum_{i \in I} \alpha_i M_i = 0 \) for some nonempty subset $I \subseteq V(D)$ and for some $\alpha_i \in \mathbb{F}_q^*$, $i \in I$. Let $D'$ be the subgraph of $D$ induced by the vertices in $I$ and $M'$ the submatrix of $M$ restricted to the rows and columns indexed by the elements of $I$. Obviously $M'$ fits $D'$, and applying this property recursively, we obtain a sequence \( (v_1, v_2, \ldots, v_s, v_{s+1}, \ldots) \), where \( (v_{s+1}, v_s) \) is an arc in $D'$ for every $s \geq 1$. Since $D'$ has a finite number of vertices, there must be a point when a vertex appears twice in the above sequence for the first time. This vertex, together with the other vertices lying between its two occurrences, form a circuit inside $D'$, which is also a circuit inside $D$.

The existence of a circuit in a digraph can be detected by using a depth-first search, the time complexity of which is linear in the size of the digraph. Hence, as a consequence of Proposition IV.12, the decision problem whether a digraph has min-rank equal to its order can be solved in polynomial time.

Remark IV.13. The second direction in the proof of Proposition IV.12 has a shorter proof as follows. Suppose that \( \minrk_q(D) \leq n - 1 \) but $D$ is acyclic. Then \( \minrk_q(D) \geq \alpha(D) = n \), by Theorem III.4. That is a contradiction. However, the original proof of Proposition IV.12 provides us with a simple and direct proof of the inequality \( \alpha(D) \leq \minrk_q(D) \) (see Corollary IV.14). This inequality for digraphs was proved indirectly via the use of $\beta_q(1, D)$ by Bar-Yossef et al. [22]. In such an indirect proof, either arguments from Information Theory are invoked [22, Theorem 7] or the corresponding confusion graph is considered [22, Lemma 37].

Corollary IV.14. For a digraph $D$ we have

\[ \alpha(D) \leq \minrk_q(D). \]

**Proof:** First note that if $D'$ is an induced subgraph of $D$ then $\minrk_q(D') \leq \minrk_q(D)$. Indeed, suppose $M$ is a matrix that fits $D$ and has rank equal to the min-rank of $D$. Then the sub-matrix $M'$ of $M$ restricted to the rows and columns indexed by the vertices in $V(D')$ is a matrix that fits $D'$. Then

\[ \minrk_q(D') \leq \text{rank}_q(M') \leq \text{rank}_q(M) = \minrk_q(D). \]

Now let $D'$ be a maximum acyclic induced subgraph of $D$ of order $\alpha(D)$. Since $D'$ is acyclic, by Proposition IV.12 we have

\[ \minrk_q(D) \geq \minrk_q(D') = |V(D')| = \alpha(D). \]

**Corollary IV.15.** For a digraph $D$, $\beta_q(D) = |V(D)|$ if and only if $D$ is acyclic. For a graph $G$, $\beta_q(G) = |V(G)|$ if and only if $G$ has no edges.

**Proof:** Suppose $\beta_q(D) = |V(D)|$. By Theorem III.4 $\minrk_q(D) = |V(D)|$. Therefore, $D$ is acyclic according to Proposition IV.12. Conversely, if $D$ is acyclic then $\beta_q(D) \geq \alpha(D) = |V(D)|$. Similar arguments hold for graphs.

E. Graphs of Min-Ranks One Less Than Their Orders

In this section, we consider (undirected) graphs. The corresponding case for digraphs is open. For a connected graph $G$ of order at least two, it is easy to see that \( mm(G) = 1 \) if and only if it is a star graph, which is defined as follows.

Definition IV.16. A graph $G = (V(G), E(G))$ is called a star graph if $|V(G)| \geq 2$ and there exists a vertex $v \in V(G)$ such that $E(G) = \{ (u, v) : u \in V(G) \setminus \{ v \} \}$.

Fig. 5: A star graph

It is straightforward to see that if $\text{mm}(G) = 1$ then $\alpha(G) = n - 1$, as $G$ is a star graph.

Proposition IV.17. Let $G$ be a connected graph of order $n \geq 2$. Then $\minrk_q(G) = n - 1$ if and only if $\text{mm}(G) = 1$ (or equivalently, $G$ is a star graph).

**Proof:** We first suppose that $\minrk_q(G) = n - 1$. By the maximum-matching bound, $n - 1 = \minrk_q(G) \leq n - \text{mm}(G)$. Therefore, $\text{mm}(G) \leq 1$. However, as $\minrk_q(G) \neq n$, by Proposition IV.11 we have $\text{mm}(G) \neq 0$. Hence, $\text{mm}(G) = 1$.

Conversely, assume that $\text{mm}(G) = 1$. By the maximum-matching bound, $\minrk_q(G) \leq n - 1$. By Theorem III.4 $\minrk_q(G) \geq \alpha(G) = n - 1$. Thus, $\minrk_q(G) = n - 1$.

Corollary IV.18. Let $G$ be a connected graph of order $n \geq 2$. Then $\beta_q(G) = n - 1$ if and only if $\text{mm}(G) = 1$ ($G$ is a star graph).

**Proof:** Suppose $\beta_q(G) = n - 1$. Then either $\minrk_q(G) = n - 1$ or $\minrk_q(G) = n$. However, by Proposition IV.11 $\minrk_q(G) = n$ implies that $G$ has no edge. As a consequence, $\beta_q(G) \geq \alpha(G) = n$, which contradicts our assumption. Hence, $\minrk_q(G) = n - 1$. According to Proposition IV.17 $\text{mm}(G) = 1$.  

1
Conversely, suppose that \( \text{mm}(G) = 1 \). According to Proposition [IV.17] we have
\[
n - 1 = \alpha(G) \leq \beta_q(G) \leq \text{minrk}_q(G) = n - 1.
\]
Hence, \( \beta_q(G) = n - 1 \).

**F. Graphs of Min-Ranks Two Less Than Their Orders**

In this section, we consider (undirected) graphs. The corresponding case for digraphs is open. Here we also employ the matching language to characterize graphs of min-ranks two less than their orders.

**Theorem IV.19.** Suppose \( G \) is a connected graph of order \( n \geq 6 \). Then \( \text{minrk}_q(G) = n - 2 \) if and only if \( \text{mm}(G) = 2 \) and \( G \) does not contain a subgraph isomorphic to the graph \( F \) depicted in Fig. 6.

![Fig. 6: The forbidden subgraph F](image)

As \( G \) does not have a matching of size three, each of the vertices \( c, f, \) and \( g \) is not adjacent to any vertex in \( V(G) \setminus V(F') \). Moreover, no pair of vertices in \( V(G) \setminus V(F') \) is adjacent for the same reason. Therefore, \( \{c, f, g\} \cup (V(G) \setminus V(F')) \) is an independent set of size \( |V(G)| - 3 \) in \( G \). Hence, \( \text{minrk}_q(G) \geq \alpha(G) \geq |V(G)| - 3 \). As \( \text{mm}(G) = 2 \), by the maximum-matching bound, \( \text{minrk}_q(G) \leq |V(G)| - 2 \). As \( G \) contains \( F' \), which is isomorphic to \( F \), by Theorem [IV.19] \( \text{minrk}_q(G) \neq |V(G)| - 2 \). Thus, \( \text{minrk}_q(G) = |V(G)| - 3 \).

**Corollary IV.20.** Theorem [IV.19] holds verbatim if we replace \( \text{minrk}_q(\cdot) \) by \( \beta_q(\cdot) \).

**Proof:** Suppose that \( \beta_q(G) = n - 2 \). Then \( \text{minrk}_q(G) \in \{n - 2, n - 1, n\} \). By Proposition [IV.11], Proposition [IV.17] and their corollaries, for \( \kappa \in \{n - 1, n\} \), \( \text{minrk}_q(G) = \kappa \) if and only if \( \beta_q(G) = \kappa \). Therefore, \( \text{minrk}_q(G) = n - 2 \). According to Theorem [IV.19], \( \text{mm}(G) = 2 \) and \( G \) does not contain a subgraph isomorphic to \( F \).

Conversely, as shown in the proof of Theorem [IV.19] (the IF direction), \( \alpha(G) = \text{minrk}_q(G) = n - 2 \). Therefore, \( \beta_q(G) = n - 2 \) by Theorem [III.3].

**V. The Hardness of the Min-Rank Problem for Digraphs**

In this section, we first prove that it is an NP-complete problem to decide whether a given digraph is fairly k-colorable (see Definition [IV.5]), for any given \( k \geq 3 \). The hardness of this problem, by Lemma [IV.3] and Corollary [IV.8], leads to the hardness of the decision problem whether a given digraph has min-rank two over \( \mathbb{F}_2 \). The fair \( k \)-coloring problem is defined formally as follows.

**Problem: FAIR \( k \)-COLORING**

**Input:** A digraph \( D \), an integer \( k \)

**Output:** True if \( D \) is fairly \( k \)-colorable, False otherwise

**Theorem V.1.** The fair \( k \)-coloring problem is NP-complete for \( k \geq 3 \).

**Proof:** This problem is obviously in NP, as the algorithm can guess a candidate for the fair coloring and verify that the candidate is indeed a fair coloring in polynomial time. For NP-hardness, we reduce the \( k \)-coloring problem to the fair \( k \)-coloring problem. Recall that the \( k \)-coloring problem is the decision problem whether a given graph is \( k \)-colorable. Suppose that \( G = (V(G), E(G)) \) is an arbitrary graph. We aim to build a digraph \( D = (V(D), E(D)) \) so that \( G \) is \( k \)-colorable if and only if \( D \) is fairly \( k \)-colorable. Suppose that \( V(G) = [n] \). For each vertex \( i \in [n] \), we build the following gadget, which is a digraph \( D_i = (V_i, E_i) \). The vertex set of \( D_i \) is
\[
V_i = \{i\} \cup \{\omega_{i,j} : j \in N^G(i)\},
\]
where \( \omega_{i,j} \) are newly introduced vertices. We refer to \( \omega_{i,j} \) as a clone (in \( D_i \)) of the vertex \( j \in [n] \). The arc set of \( D_i \) is
\[
E_i = \{(\omega_{i,j}, i) : j \in N^G(i)\}.
\]
Let \( N^G(i) = \{i_1, i_2, \ldots, i_{n_i}\} \). Then \( D_i \) can be drawn as in Fig. 8.

![Fig. 8: Gadget \( D_i \) for each vertex \( i \) of \( G \)](image)

Additionally, we also introduce \( n \) new vertices \( p_1, p_2, \ldots, p_n \). The digraph \( D = (V(D), E(D)) \) is built as follows. The vertex set of \( D \) is
\[
V(D) = (\bigcup_{i=1}^n V_i) \cup \{p_1, p_2, \ldots, p_n\}.
\]
Let
\[
Q_i = \{(p_i, i)\} \cup \{(p_i, \omega_{i,i'}) : i' \in [n], i \in N^G(i')\}
\]
be the set consisting of \( (p_i, i) \) and the arcs that connect \( p_i \) and all the clones \( \omega_{i,i'} \) of \( i \). The arc set of \( D \) is then defined to be
\[
E(D) = (\bigcup_{i=1}^n E_i) \cup (\bigcup_{i=1}^n Q_i).
\]
We now check if (C2) (see Definition IV.5) is also satisfied. We claim that \( \phi_D \) is a fair \( k \)-coloring for \( D \). We first verify that (C1), if \( \{i,j\} \in \mathcal{E}(G) \), that is, \( j \in N^G(i) \), then

\[
\phi_D(i) \neq \phi_D(i') \implies \phi_D(j) \neq \phi_D(j').
\]

Hence, if we define \( \phi_G : [n] \to [k] \) by \( \phi_G(i) = \phi_D(i) \) for all \( i \in [n] \), then it is a \( k \)-coloring of \( G \). Thus \( G \) is \( k \)-colorable.

Finally, notice that the order of \( D \) is a polynomial with respect to the order of \( G \). More specifically, \( |V(D)| = 2|V(G)| + 2|E(G)| \) and \( |E(D)| = |V(G)| + 4|E(G)| \). Moreover, building \( D \) from \( G \), and also obtaining a coloring of \( G \) from a coloring of \( D \), can be done in polynomial time with respect to the order of \( G \). Since the \( k \)-coloring problem \( (k \geq 3) \) is NP-hard [28], we conclude that the fair \( k \)-coloring problem is also NP-hard.

According to Theorem V.1 and the work by Blasiak et al. [25] (see the discussion after Corollary IV.8), we obtain the following.

**Theorem V.2.** Let \( D \) be an arbitrary digraph. Then the decision problem whether minrk\(_2(D) = 2 \) is NP-complete. However, the decision problem whether \( \beta_2(D) = 2 \) can be solved in polynomial time.

Recall that by contrast, for a graph \( G \), it was observed by Peeters [12] that \( G \) has min-rank two if and only if \( G \) is a bipartite graph and \( G \) is not a complete graph, which can be verified in polynomial time (see, for instance, West [17, p. 495]). Note that a graph is bipartite if and only if it is 2-colorable. This fact can also be derived by applying Theorem [27.7] to the digraph obtained from \( G \) by replacing each edge of \( G \) by two arcs of opposite directions.

### VI. Circuit-Packing Bound

In this section we introduce a new upper bound for the min-rank of a digraph. This bound reveals some new families of digraphs whose min-ranks are computable in polynomial time.

**A. The Bound**

Let \( \nu_0(D) \) be the circuit packing number of \( D \), namely, the maximum number of vertex-disjoint circuits in \( D \). Below, we establish an upper bound on min-ranks of digraphs, which uses the circuit packing number. This bound was first presented by Chaudhry et al. in [21], and was obtained independently by the authors of this paper approximately at the same time.

**Proposition VI.1** (Circuit-packing bound). The following holds for every digraph \( D \) of order \( n \):

\[
\text{minrk}_q(D) \leq n - \nu_0(D).
\]

**Proof:** Suppose \( D \) contains \( \nu_0(D) \) vertex-disjoint circuits \( C_1, C_2, \ldots, C_{\nu_0(D)} \), where

\[
C_i = \{u_{i,1}, u_{i,2}, \ldots, u_{i,n_i}\}, \quad i \in [\nu_0(D)], \quad 2 \leq n_i \leq n.
\]
Let $V(C_i) = \{u_{i,1}, u_{i,2}, \ldots, u_{i,n_i}\}$ ($i \in [\nu_0(D)]$). We construct a matrix $M$ fitting $D$ as follows. Let
\[
A = V(D) \cup [\nu_0(D)]V(C_i).
\]
For $v \in A$ let $M_{v} = e_v$. For $i \in [\nu_0(D)]$ and $s \in [n_i - 1]$, let
\[
M_{u_{i,s}} = e_{u_{i,s}} - e_{u_{i,s+1}},
\]
and let
\[
M_{u_{i,n_i}} = e_{u_{i,1}} - e_{u_{i,n_i}}.
\]
Clearly, $M$ fits $D$. Moreover, as
\[
M_{u_{i,n_i}} = \sum_{s=1}^{n_i-1} M_{u_{i,s}} = \nu_0(D),
\]
we have
\[
\text{rank}_q(M_{\nu_0(D)}) \leq n_i - 1
\]
for all $i \in [\nu_0(D)]$. Since $V(C_i)$, $s \in [\nu_0(D)]$, are pairwise disjoint, we have
\[
\text{rank}_q(M) \leq \sum_{i=1}^{\nu_0(D)} \text{rank}_q(M_{\nu_0(D)}) + \text{rank}_q(M_A)
\]
\[
\leq \sum_{i=1}^{\nu_0(D)} (n_i - 1) + \left(n - \sum_{i=1}^{\nu_0(D)} n_i\right)
\]
\[
= n - \nu_0(D).
\]
Thus, $\text{minrk}_q(D) \leq n - \nu_0(D)$.

Whereas for graphs the clique-cover bound is the best known bound, for digraphs that are not symmetric, this is not the case. The worst scenario for the clique-cover bound is when the digraph has no two arcs of opposite directions. For such a digraph, this bound becomes trivial, as the size of a feedback vertex (arc, respectively) set is when the digraph has no two arcs of opposite directions.

**Example VI.2.** Let $D_k$ be the digraph of order $n = 3k$ depicted in Fig. 11. As there are no arcs of opposite directions, all cliques in $D_k$ are of cardinality one. Therefore, the clique-cover bound gives $\text{minrk}_q(D_k) \leq 3k$. On the other hand, as $D_k$ contains $k$ vertex-disjoint circuits, namely $C_i = (3i + 1, 3i + 2, 3i + 3)$ for $i = 0, 1, \ldots, k - 1$, the circuit-packing bound yields $\text{minrk}_q(D_k) \leq 2k = 3k - k$. The gap between the two bounds is one third of the order of the digraph.

**B. Digraphs Attaining Circuit-Packing Bound**

In this subsection, we present several new examples of families of digraphs that attain the circuit-packing bound.

A feedback vertex (arc, respectively) set of $D$ is a set of vertices (arcs, respectively) whose removal destroys all circuits in $D$. Let $\tau_0(D)$ ($\tau_1(D)$, respectively) denote the minimum size of a feedback vertex (arc, respectively) set of $D$. Then it is clear that $\alpha(D) = n - \tau_0(D)$.

**Corollary VI.3.** If $\nu_0(D) = \tau_0(D)$ then
\[
\text{minrk}_q(D) = n - \nu_0(D) = n - \tau_0(D).
\]

**Proof:** By Corollary IV.13 and Proposition VI.11 we have
\[
n - \tau_0(D) \leq \text{minrk}_q(D) \leq n - \nu_0(D).
\]
Hence, the proof follows.

When $D$ satisfies $\nu_0(D) = \tau_0(D)$, we say that $D$ satisfies the min-max vertex equality. In that case, the circuit-packing bound is tight. Similarly, let $\nu_1(D)$ denote the maximum number of arc-disjoint circuits in $D$. We say that $D$ satisfies the min-max arc equality if $\nu_1(D) = \tau_1(D)$.

The first example of digraphs for which the circuit-packing bound is tight is the fully reducible flow digraphs [29]. A flow digraph is a digraph that contains a special vertex called root, from which any vertex is reachable by a directed path. A fully reducible flow digraph is a flow digraph that satisfies the property that every circuit $C$ in the digraph has a unique vertex $v_C$ such that every directed path from the root to a vertex of $C$ must contain $v_C$. Interestingly, it was proved by Shamir [30] that there is a linear time algorithm to find $\nu_0(D) (= \tau_0(D))$ for a fully reducible flow digraph $D$. As a consequence, the min-rank of a fully reducible flow digraph (recognizable in polynomial time with respect to its size [31]) can be calculated in linear time with respect to its size.

The second example of digraphs that satisfy the min-max vertex equality is the connectively reducible digraphs [32]. This family of digraphs actually generalizes both the family of fully reducible flow digraphs and the family of cyclically reducible digraphs [33]. A polynomial time algorithm was provided by Szwarzfiter [32] to recognize a member of this family and subsequently find a maximum set of vertex-disjoint circuits as well as a minimum feedback vertex set. Therefore, by Corollary VI.3 (1) holds for a connectively reducible digraph $D$. Moreover, $\text{minrk}_q(D)$ can be found in polynomial time.

The third example of digraphs for which the circuit-packing bound is tight is the digraphs that pack [34]. A digraph packs if the min-max vertex equality holds for all of its subgraphs. The digraphs in this family are exactly ones that have no minor isomorphic to an odd double circuit or $F_7$, a special digraph of order 7 (interested readers may refer to [34] for more details, also for a structural characterization of this family of digraphs). For instance, strongly planar digraphs [34] belong to this family. As far as we know, there are no known polynomial time algorithms to find a minimum feedback vertex set of a digraph that packs.

The other examples of digraphs for which the circuit-packing bound is tight are the line digraphs of planar digraphs, of fully reducible flow digraphs, and of (special) Eulerian digraphs [35].

**Definition VI.4.** Let $D = \langle V(D), E(D) \rangle$ be a digraph. Then the digraph $\mathcal{L} = \langle V(\mathcal{L}), E(\mathcal{L}) \rangle$ with $V(\mathcal{L}) = E(D)$ and $E(\mathcal{L}) = \{(e, e') : e = (u, v) \in E(D), e' = (v, w) \in E(D)\}$. 
Lemma VI.5. \( \nu_0(\mathcal{L}(D)) = \nu_1(D) \).

Proof:
1) \( \nu_0(\mathcal{L}(D)) \geq \nu_1(D) \). It suffices to show that the existence of a set of arc-disjoint circuits in \( D \) implies the existence of a set of vertex-disjoint circuits of the same size in \( \mathcal{L}(D) \). Let \( \{C_1, C_2, \ldots, C_k\} \) be a set of arc-disjoint circuits in \( D \), where \( C_i = (v_{i,1}, v_{i,2}, \ldots, v_{i,r_i}), r_i \geq 2, i \in [k] \). Let \( e_{i,j} = (v_{i,j}, v_{i,j+1}), \) for \( i \in [k] \) and \( j \in [r_i - 1] \). Moreover, let \( e_{i,r_i} = (v_{i,r_i}, v_{i,1}) \) for \( i \in [k] \). Let \( C'_i = (e_{i,1}, e_{i,2}, \ldots, e_{i,r_i}) \) for \( i \in [k] \). Then \( C'_i \) is also a circuit in \( \mathcal{L}(D) \) for every \( i \in [k] \). Moreover, as the circuits \( C_1, C_2, \ldots, C_k \) share no common edges in \( D \), we deduce that \( C'_1, C'_2, \ldots, C'_k \) share no common vertices in \( \mathcal{L}(D) \). Therefore, they form a set of \( k \) vertex-disjoint circuits in \( \mathcal{L}(D) \).

2) \( \nu_0(\mathcal{L}(D)) \leq \nu_1(D) \). It suffices to show that the existence of a set of vertex-disjoint circuits in \( \mathcal{L}(D) \) implies the existence of a set of arc-disjoint circuits of the same size in \( D \). Let \( \{C'_1, C'_2, \ldots, C'_k\} \) be a set of vertex-disjoint circuits in \( \mathcal{L}(D) \), where \( C'_i = (e_{i,1}, e_{i,2}, \ldots, e_{i,r_i}) \) for \( i \in [k] \). Suppose that \( e_{i,j} = (v_{i,j}, v_{i,j+1}) \in \mathcal{E}(D) \) for \( i \in [k] \) and \( j \in [r_i] \), where \( v_{i,j} \) and \( v_{i,j+1} \) are vertices of \( D \). Then \( v_{i,j+1} \equiv v_{i,j} \) for \( i \in [k] \). For each \( i \in [k] \), consider the sequence of (possibly repeated) vertices \( v_{i,1}, v_{i,2}, \ldots, v_{i,r_i+1} \).

Since \( v_{i,1} \equiv v_{i,j+1} \) and \( (v_{i,j}, v_{i,j+1}) \in \mathcal{E}(D) \) for all \( j \in [r_i] \), there exist \( j_0 < j_1 \) such that
- \( 1 \leq j_0 < j_1 \leq r_i \);
- \( v_{i,j_0} \equiv v_{i,j_1+1} \);
- \( v_{i,j_0}, v_{i,j_0+1}, \ldots, v_{i,j_1} \) are distinct.
Then \( C'_i = (v_{i,j_0}, v_{i,j_0+1}, \ldots, v_{i,j_1}) \) is a circuit in \( D \). Since the circuits \( C'_1, C'_2, \ldots, C'_k \) share no common vertices in \( \mathcal{L}(D) \), we obtain that the circuits \( C_1, C_2, \ldots, C_k \) share no common edges in \( D \).

Lemma VI.6. \( \tau_0(\mathcal{L}(D)) = \tau_1(D) \).

Proof: Let \( F = \{e_1, e_2, \ldots, e_k\} \), where \( e_i \in \mathcal{E}(D) \) for \( i \in [k] \), be an arbitrary set of arcs of \( D \). We can also view \( F \) as a set of vertices of \( \mathcal{L}(D) \). It suffices to show that \( F \) is a feedback arc set of \( D \) if and only if \( F \) is a feedback vertex set of \( \mathcal{L}(D) \), for every such set \( F \).

Let \( D - F \) be the digraph obtained from \( D \) by removing all arcs in \( F \). Let \( \mathcal{L}(D) - F = \mathcal{L}(D) - F \) be the digraph obtained from \( \mathcal{L}(D) \) by removing all vertices in \( F \). Then \( \mathcal{L}(D) - F = \mathcal{L}(D - F) \). As shown in the proof of Lemma VI.5, the existence of a circuit in \( D - F \) would result in the existence of a circuit in \( \mathcal{L}(D) - F \) and vice versa. Therefore, \( D - F \) is acyclic if and only if \( \mathcal{L}(D) - F \) is acyclic. Thus, \( F \) is a feedback arc set of \( D \) if and only if \( F \) is a feedback vertex set of \( \mathcal{L}(D) \).

Proposition VI.7. Let \( D \) be a digraph. If \( \nu_1(D) = \tau_1(D) \) then \( \nu_0(\mathcal{L}(D)) = \tau_0(\mathcal{L}(D)) \) and \( \minrk_q(\mathcal{L}(D)) = |\mathcal{E}(D)| - \nu_1(D) \).

Proof: Suppose that \( \nu_1(D) = \tau_1(D) \). By Lemma VI.5 and Lemma VI.6 \( \nu_0(\mathcal{L}(D)) = \tau_0(\mathcal{L}(D)) \). Therefore, by applying Corollary VI.3 to \( \mathcal{L}(D) \) we obtain \( \minrk_q(\mathcal{L}(D)) = |V(\mathcal{L}(D))| - \nu_0(\mathcal{L}(D)) = |\mathcal{E}(D)| - \nu_1(D) \).

Definition VI.8. A digraph that can be drawn on a plane in such a way that its (arcs) edges intersect only at their endpoints is called planar.

It is known that the min-max arc equality is satisfied for planar digraphs [36], for fully reducible flow digraphs [37], and for a special family of Eulerian digraphs [35]. Therefore, by Proposition VI.7, the min-max vertex equality is satisfied for the line digraphs of the members of these families. In summary, we have the following.

Corollary VI.9. The circuit-packing bound is tight for the following families of digraphs: connectively reducible digraphs, digraphs that pack, line digraphs of planar digraphs, line digraphs of fully reducible flow digraphs, and line digraphs of special Eulerian digraphs.

Consider the ICSI instances described by digraphs \( D \) with \( \minrk_q(D) = \alpha(D) \). By Theorem III.3 \( \minrk_q(D) = \beta_q(D) \). Hence, for such instances, scalar linear index codes are as...
good as vector nonlinear index codes, in terms of transmission rates. Thus, for the ICSI instances described by families of digraphs listed in Corollary VI.9 scalar linear index codes achieve the best possible transmission rates. Previously, only perfect graphs and acyclic digraphs were known to have this property [22].

**Definition VI.10.** A digraph is called partially planar if all of its strongly connected components are planar.

Since the strongly connected components of a planar digraph are also planar, a planar digraph is partially planar. However, the converse is not always true, as shown in Fig. 13.

![Fig. 13: A partially planar digraph that is not planar](image)

**Proposition VI.11.** There is a polynomial time algorithm to recognize the line digraph of a partially planar digraph and subsequently determine its min-rank.

**Proof:**

1) **Recognition Phase:**
There is a one-to-one correspondence between the set of strongly connected components of order at least two of $\mathcal{D}$ and the set of strongly connected components of $\mathcal{L}(\mathcal{D})$ in the following sense. If $\mathcal{D}_i$'s, $i \in [k]$, are all strongly connected components of $\mathcal{D}$ each of which contains at least two vertices, then $\mathcal{L}(\mathcal{D}_i)$'s, $i \in [k]$, are all strongly connected components of $\mathcal{L}(\mathcal{D})$. Therefore, to determine whether a given digraph $\mathcal{L}$ is the line digraph of a partially planar digraph, it suffices to determine whether each of its strongly connected components $\mathcal{L}_i$ ($i \in [k]$) is the line digraph of a planar digraph. Note also that we can find all strongly connected components of a digraph in linear time in the number of edges [38].

For each $i \in [k]$, employing a polynomial time algorithm, we can determine whether $\mathcal{L}_i$ is a line digraph of a digraph [49]. If the answer is YES, then the algorithm also outputs a digraph $\mathcal{D}'_i$, which is a root digraph of $\mathcal{L}_i$ and is strongly connected.

Suppose $\mathcal{L} = \mathcal{L}(\mathcal{D})$, where $\mathcal{D}$ is a digraph. Moreover, let $\mathcal{L}_i = \mathcal{L}(\mathcal{D}_i)$, where $\mathcal{D}_i$'s, $i \in [k]$, are all strongly connected components of $\mathcal{D}$ of order at least two. By [40] Theorem 3, $\mathcal{D}'_i$ and $\mathcal{D}_i$ are actually isomorphic, $i \in [k]$. Hence, to complete the Recognition Phase, one needs to test the planarity of $\mathcal{D}'_i$ for every $i \in [k]$. It is well known that this task can be done in time linear in the size of $\mathcal{D}$ [41]. Thus, the Recognition Phase can be done in polynomial time.

2) **Min-Rank Computation Phase:**

Upon the completion of the Recognition Phase, if it is confirmed that $\mathcal{L}$ is indeed the line digraph of a partially planar digraph, then the second phase is executed to compute $\minrk_q(\mathcal{L})$. We show that this phase can also be done in polynomial time. Indeed, by Lemma IV.2 it suffices to show that $\minrk_q(\mathcal{L}_i)$ for $i \in [k]$ can be found in polynomial time.

On the one hand, since $\mathcal{D}'_i$ (which is isomorphic to $\mathcal{D}_i$) is planar, as shown by Lucchesi and Younger [36], $\nu_1(\mathcal{D}'_i) = \tau_1(\mathcal{D}'_i)$. Therefore, by Proposition VI.7

$$\minrk_q(\mathcal{L}_i) = |\mathcal{E}(\mathcal{D}'_i)| - \nu_1(\mathcal{D}'_i).$$

On the other hand, $\nu_1(\mathcal{D}'_i)$ can be computed in polynomial time [42]. Therefore $\minrk_q(\mathcal{L}_i)$ for each $i \in [k]$ can be computed in polynomial time. Thus, $\minrk_q(\mathcal{L})$ can be found in polynomial time.

In summary, we have the following.

**Corollary VI.12.** There are polynomial time algorithms to recognize a member and subsequently determine the min-rank of that member of the following families of digraphs: connectedly reducible digraphs (which includes fully reducible flow digraphs and cyclically reducible digraphs), and line digraphs of partially planar digraphs.

**VII. Conclusion and Open Problems**

We have characterized the ICSI instances whose optimal scalar linear index codes have near-extreme transmission rates. Except for one case, these ICSI instances are also those that have near-extreme vector nonlinear transmission rates. We have also introduced an upper bound on min-ranks of digraphs. Based on this bound, we have discovered several new families of digraphs whose min-ranks can be found in polynomial time.

We state below a couple of interesting open problems for future research.

**Open Problem I:** Examine the hardness of the decision problem whether a given digraph has min-rank two over a nonbinary field $\mathbb{F}_q$.

**Open Problem II:** Examine the hardness of the problem of finding $\beta_q(\mathcal{D})$ for a given digraph $\mathcal{D}$.

**Open Problem III:** Find new families of digraphs whose min-ranks can be found in polynomial time.

**VIII. Acknowledgment**

The authors wish to thank M. Langberg for providing the preprints [14, 15].

IX. APPENDIX

Proof of Theorem 4.19 For the ONLY IF direction, suppose that \( \minrk(G) = n - 2 \). By the maximum-matching bound, \( n - 2 \leq n - \mm(G) \). Hence \( \mm(G) \leq 2 \). As \( \mm(G) \in \{0, 1\} \) and \( |V(G)| \geq 6 \) imply that either \( G \) has no edges (\( \minrk(G) = n - 2 = 0 \)) or \( G \) is a star graph (\( \minrk(G) = n - 1 = n - 2 \)).

Moreover, as the graph \( F \) has min-rank three less than its order, \( G \) should not contain any subgraph isomorphic to \( F \). Indeed, suppose for otherwise that \( F' \) is a subgraph of \( G \) and \( F' \) is isomorphic to \( F \).

Consider the following block diagonal matrix \( M \) with two blocks \( B_1 \) and \( B_2 \). The first block \( B_1 \), a \( 6 \times 6 \) matrix, corresponds to the rows and columns labeled by the vertices in \( F' \). Moreover, we choose \( B_2 \) so that it has \( q \)-rank three. This is possible since \( F' \) is isomorphic to \( F \) and \( \minrk(F) = 3 \).

(Not that \( 3 = \alpha(F) \leq \minrk(F) \leq \cc(F) = 3 \) implies that \( \minrk(F) = 3 \)). The second block \( B_2 \) is chosen to be an \((n - 6) \times (n - 6)\) identity matrix. It corresponds to the rows and columns labeled by the vertices in \( V(G) \setminus V(F') \). Then \( M \) fits \( G \) and moreover,

\[
\rank_q(M) = \rank_q(B_1) + \rank_q(B_2)
\]

\[
= 3 + (n - 6)
\]

\[
= n - 3.
\]

This implies that \( \minrk(G) \leq n - 3 < n - 2 \), which is impossible.

We now turn to the IF direction. Suppose that \( \mm(G) = 2 \) and \( G \) does not contain any subgraph isomorphic to \( F \). Then by the maximum-matching bound, \( \minrk(G) \leq n - 2 \). As \( \alpha(G) \leq \minrk(G) \), it suffices to show that \( \alpha(G) = n - 2 \).

Let \( \{a, b\} \) and \( \{c, d\} \) be the two edges of a maximum matching \( M \) in \( G \). Let \( U = \{a, b, c, d\} \) and \( V = V(G) \setminus U \).
As $G$ has at least six vertices, suppose that $V = \{f, g, \ldots\}$, where $f \neq g$. Since $M$ is a maximum matching, $V$ must be an independent set in $G$. The idea is to show that we can always find two nonadjacent vertices in $U$ that are not adjacent to any vertex in $V$. Such two vertices can be added to $V$ to obtain an independent set of size $n - 2$, which establishes the proof. We refer to such a pair of vertices as an independent pair.

For disjoint subsets $I$ and $J$ of $V(G)$, let

$$s_G(I, J) = |\{(i, j) : i \in I, j \in J, \{i, j\} \in E(G)\}|.$$  

Based on how the vertices in $U$ are connected to each other, we consider the following five cases. Note that we only consider non-isomorphic configurations.

**Case 1:** $s_G(\{a, b\}, \{c, d\}) = 0.$

![Fig. 14: Case 1](image)

There are four candidates for an independent pair, namely $\{a, c\}$, $\{a, d\}$, $\{b, c\}$, $\{b, d\}$. All of these pairs fail to be an independent pair if and only if either both $a$ and $b$ are adjacent to some vertices in $V$ or both $c$ and $d$ are adjacent to some vertices in $V$. We show that either case never happens, by contradiction.

Suppose both $a$ and $b$ are adjacent to some vertices in $V$. (The case when both $c$ and $d$ are adjacent to some vertices in $V$ is investigated analogously.) Without loss of generality, assume that $a$ and $f$ are adjacent. Then $b$ must be adjacent to $f$ but not to any other vertex in $V$. Indeed, if $b$ is adjacent to $h \in V$, $h \neq f$, then the set of three edges $\{a, f\}$, $\{b, h\}$, and $\{c, d\}$ form a matching of size three, which is impossible since $\text{mm}(G) = 2$. Similarly, $a$ should not be adjacent to any other vertex in $V$ rather than $f$.

As $G$ is connected, $f$ must be adjacent to either $c$ or $d$. Without loss of generality, suppose $f$ and $c$ are adjacent. On the one hand, since $G$ is connected, $g$ must be adjacent to some vertex in $U$. On the other hand, $g$ cannot be adjacent to any vertex in $U$, as

- if $g$ and $a$ are adjacent, then $\{a, g\}$, $\{b, f\}$, and $\{c, d\}$ form a matching of size three, which is impossible;
- if $g$ and $b$ are adjacent, then $\{a, f\}$, $\{b, g\}$, and $\{c, d\}$ form a matching of size three, which is impossible;
- if $g$ and $c$ are adjacent, then $G$ has a subgraph isomorphic to $F$ (see Fig. 15), which is impossible;
- if $g$ and $d$ are adjacent, then $\{a, b\}$, $\{c, f\}$, and $\{d, g\}$ form a matching of size three, which is impossible.

We obtain a contradiction.

**Case 2:** $s_G(\{a, b\}, \{c, d\}) = 1$. Without loss of generality, suppose that $\{b, c\}$ is the only edge that connects $\{a, b\}$ and $\{c, d\}$. There are three candidates for an independent pair, namely $\{a, c\}$, $\{a, d\}$, and $\{b, d\}$. All of these three pairs fail to be an independent pair only if at least one of the pairs $\{a, b\}$, $\{a, d\}$, and $\{c, d\}$ has both vertices adjacent to some vertices in $V$. We show below that this scenario cannot happen.

1) Assume that both $a$ and $b$ are adjacent to some vertices in $V$. Suppose without loss of generality that $a$ and $f$ are adjacent. Then the same argument as in Case 1 establishes that $b$ must be adjacent to $f$ but not to any other vertex in $V$. On the one hand, as $G$ is connected, $g$ must be adjacent to some vertex in $U$. On the other hand, as $\text{mm}(G) = 2$, $g$ should not be adjacent to any vertex among $a$, $b$, and $d$. Moreover, $g$ and $c$ cannot be adjacent, for otherwise $G$ would contain a subgraph isomorphic to $F$ (see Fig 15). We obtain a contradiction.

2) Assume that both $a$ and $d$ are adjacent to some vertices in $V$. Suppose without loss of generality that $a$ and $f$ are adjacent. As there are no matchings of size three in $G$, $d$ is adjacent to $f$ but not to any other vertex in $V$. Also, $g$ is not adjacent to any vertex in $U$. However, this would imply that $g$ is an isolated vertex of $G$, which is impossible as $G$ is connected.

3) Assume that both $c$ and $d$ are adjacent to some vertices in $V$. This sub-case is completely similar to the first sub-case.

**Case 3:** $s_G(\{a, b\}, \{c, d\}) = 2$ and the two edges that connect $\{a, b\}$ and $\{c, d\}$ share one common vertex. Without loss of generality suppose that these two edges are $\{b, c\}$ and $\{b, d\}$.

There are two candidates for an independent pair, namely $\{a, c\}$ and $\{a, d\}$. It suffices to show that $a$ is not adjacent to any vertex in $V$ and either $c$ or $d$ is not adjacent to any vertex in $V$.

Suppose that $a$ is adjacent to a vertex, say $f$, in $V$. As $\text{mm}(G) = 2$, we deduce that $g$ is not adjacent to any vertex among $b$, $c$, and $d$. Also, since $G$ does not contain a subgraph isomorphic to $F$, we deduce that $g$ cannot be adjacent to $a$ (see Fig. 17). Hence $g$ is an isolated vertex of $G$, which is impossible as $G$ is connected.

Now suppose that both $c$ and $d$ are adjacent to some vertices in $V$. Without loss of generality, suppose that $c$ is adjacent to
Case 4: \( s_G(\{a, b\}, \{c, d\}) = 2 \) and the two edges that connect \{a, b\} and \{c, d\} share no common vertices. Suppose, without loss of generality, that these two edges are \{a, d\} and \{b, c\}.

There are two candidates for an independent pair, namely \{a, c\} and \{b, d\}. Both of these pairs fail to be an independent pair if and only if at least one of the four pairs \{a, b\}, \{a, d\}, \{c, b\}, and \{c, d\} has both vertices adjacent to some vertices in \( V \). By symmetry, it suffices to show that the scenario when both \( a \) and \( b \) are adjacent to some vertices in \( V \) never happens.

Suppose now that \( a \) and \( b \) are adjacent to some vertices in \( V \).

Case 5: \( s_G(\{a, b\}, \{c, d\}) = 3 \). Without loss of generality, suppose that \{a, d\}, \{b, c\}, and \{b, d\} are the edges that connect \{a, b\} and \{c, d\}. The only candidate for an independent pair is \{a, c\}. We prove by contradiction that both \( a \) and \( c \) are not adjacent to any vertex in \( V \). By symmetry, it suffices to verify this property for only one of them.

Suppose that \( a \) is adjacent to some vertex in \( V \). Let \( a \) be adjacent to \( f \).

As \( \text{mm}(G) = 2 \) and \( G \) is connected, \( g \) must be adjacent to \( a \). However, \( G \) now contains a subgraph whose edge set consists of \{b, c\}, \{b, d\}, \{c, d\}, \{b, a\}, \{a, f\}, \{a, g\}, which is isomorphic to \( F \) (see Fig. 20). This contradicts our assumption.

Case 6: \( s_G(\{a, b\}, \{c, d\}) = 4 \). In this case, the subgraph of \( G \) induced by \{a, b, c, d\} is a complete graph.

As \( G \) is connected, both \( f \) and \( g \) must be adjacent to some vertices in \( U \). If \( f \) and \( g \) are adjacent to the same vertex in \( U \), then \( G \) contains a subgraph isomorphic to \( F \), which contradicts our assumption. For instance, if both \( f \) and \( g \) are adjacent to \( a \), then this subgraph has vertex set \{a, b, c, d, f, g\} and edge set consisting of the edges \{b, c\}, \{c, d\}, \{b, d\}, \{b, a\}, \{a, f\}, \{a, g\}. It is also easy to verify that if \( f \) and \( g \) are adjacent to different vertices in \( U \), then \( G \) contains a matching of size three. This contradicts our assumption that \( \text{mm}(G) = 2 \). Thus, Case 6 never happens. □
