Mimivirus in Pneumonia Patients
Bernard La Scola,* Thomas J. Marrie,† Jean-Pierre Auffray,‡ and Didier Raoult*

Mimivirus, the largest virus known to date, is an ame- bal pathogen—like Legionella sp. When Mimivirus was used as an antigen in a migration inhibition factor assay, sero- conversion was found in patients with both community- and hospital-acquired pneumonia. Mimivirus DNA was found in respiratory samples of a patient with hospital-acquired pneumonia.

The causative agent of pneumonia, the leading cause of infection-related death throughout the world, is unknown in 20% to 50% of cases (1). Therefore, identifying new causative agents of both community- and hospital-acquired pneumonia is a major public health goal. Aquatic bacteria such as Legionella spp., Pseudomonas spp., Stenotrophomonas spp., Burkholderia spp., and Acinetobacter spp. colonize hospital water supplies. These bacteria, such as L. pneumophila, have been causally associated with both hospital- and community-acquired pneumonia. Legionella spp. and other bacteria are associated with free-living amebas in natural and hospital aquatic environments (2). Bacteria that resist phagocytic destruction by amebas and are found in aerosolized water are potential agents of pneumonia (3). Ameba-associated bacteria other than L. pneumophila, including other Legionella spp., new α-proteobacteria belonging to the Bradyrhizobiaceae (Bosea massiliensis) family, and members of the genus Parachlamydia might be implicated in hospital-acquired pneumonia (4–6).

In strict intraamebal bacteria, we found Legionella-like amebal pathogens (7), Parachlamydia acanthamebae (8), and a giant virus resembling gram-positive cocci that we named Mimivirus (9). The Mimivirus’s genome is larger than that of Mycoplasma and genome sequencing is finished (10). Because we found antibodies against several ameba-associated bacteria in patients with community- and hospital-acquired pneumonia (3,4) in previous studies, we tested for antibodies to Mimivirus by using a microimmuno- fluorescence assay on serum samples from patients with community- and hospital-acquired pneumonia. DNA of Mimivirus was also found in the bronchoalveolar lavage specimens of patients with hospital-acquired pneumonia.

The Study
We studied serum samples from 376 Canadian patients with community-acquired pneumonia (121 ambulatory and 255 hospitalized) and from 511 healthy control subjects. Extensive clinical data were available for 104 patients with community-acquired pneumonia. All of these samples were previously tested for other pneumonia agents (4). To prepare antigen for microimmunofluorescence study, Mimivirus was grown in Acanthameba polyphaga strain Linc AP-1 in 75-cm² cell culture flasks with peptone yeast extract glucose medium as previously described (11). After amebral lysis occurred, unlysed amebas were removed by low speed centrifugation at 100 g for 15 min. Mimivirus particles present in supernatant were centrifuged at 4,000 g for 30 min and washed 3 times in phosphate-buffered saline (PBS). The pellet obtained after the last washing was then resuspended in PBS at 2 mg/mL concentration of protein and used as antigen in microimmunofluorescence assay under previously described conditions (5). Evidence of serologic reaction to Mimivirus was defined as: 1) seroconversion from <1:50 to ≥1:100 between acute-phase and convalescent-phase serum samples or a 4-fold rise in antibody titer between acute-phase and convalescent-phase serum samples, or 2) a single or stable titer of ≥1:400. The cut-off titer for single serum was chosen to have <2.5% positive rate in control subjects. We also tested paired serum samples from 26 patients with intensive care unit (ICU)-acquired pneumonia for a 1-year period and 50 paired serum samples from patients in our institution to determine antibodies to Rickettsia spp. as controls.

To verify that antibodies against Mimivirus in patients with pneumonia recognize Mimivirus particles specifically, a serum sample of 1 of these patients was used to detect Mimivirus particles by immunogold technique as previously described (12). Two serum samples of patients who did not have detectable antibodies against Mimivirus were used as controls. Grids were incubated briefly twice in incubation buffer (PBS with 0.2% bovine serum albumin) for 5 min, then for 15 min in lysine buffer (PBS with 0.05 mol lysin). Grids were washed twice in incubation buffer for 5 min, then incubated for 3 h at 37°C in patients’ diluted samples (diluted 1/1,000 in incubation buffer with 3% nonfat dry milk). Grids were washed 6 times for 5 min in incubation buffer, then incubated for 2 h at 37°C in goat antihuman immunoglobulin (IgG)-gold conjugate (Aurion Biovalley, Marne la Vallee, France) diluted 1/20 in incubation buffer with 3% nonfat dry milk. Grids were washed 6 times for 5 min in incubation buffer, then twice in PBS for 5 min. Grids were then immersed twice in glutaraldehyde (2% in PBS) for 5 min, rinsed 3 times in distilled water for 5 min, treated by R-GENT SE-EM (Aurion Biovalley) for 25 min, then rinsed 3 times in distilled water for 5 min before being stained with uranyl acetate before examination.
Genomic DNA of Mimivirus was found in bronchoalveolar lavage specimens from patients in the ICU of the Ste. Marguerite Hospital, Marseilles, France; serologic reaction was studied in serum samples of the patients for 1 year. The study was retrospective; samples were tested anonymously from 12 to 18 months after sampling. Mimivirus was found in bronchoalveolar lavage specimens from 1 of 32 patients with ICU-acquired pneumonia and none in specimens from 21 intubated control patients in ICU who did not have pneumonia (5). We designed 4 primer pairs chosen from the genome sequence of Mimivirus. To avoid any contamination, we used a nested polymerase chain reaction (PCR), previously described as “suicide-PCR,” that incorporates 2 primer pairs used only once without positive control, followed by sequencing and comparing to the targeted sequence (13). DNA from patient and control BAL specimens, 3 water samples, and a suspension of A. polyphaga were extracted by using the QIAmp Tissue kit (QIAGEN GmbH, Hilden, Germany). DNA extracts from selected pathogens, including agents that are most commonly encountered in cases of hospital-acquired pneumonia (14), were tested: Enterobacter aerogenes, Proteus mirabilis, Citrobacter freundii, Escherichia coli, Citrobacter koseri, Klebsiella pneumoniae, Enterobacter cloacae, Serratia marcescens, Haemophilus influenzae, Moraxella catarrhalis, Acinetobacter baumanii, Stenotrophomonas maltophilia, Pseudomonas aeruginosa, Bacteroides fragilis, Prevotella intermedia, Streptococcus pneumoniae, Streptococcus oralis, Staphylococcus aureus, Staphylococcus epidermidis, Candida albicans, CMV, HSV1, and adenovirus. Extracted DNA was used as template with primers BCFE (5′-TTATTGGTCCCAATGCTACTC-3′) and BCRE (5′-TAATTACCATACGCAATTCCTG-3′) as external primers and BCFI (5′-TGTCATTCCAAATGTTAACGAAAC-3′) and BCRI (5′-GCCATAGCATTTAGTCCGAAAG-3′) as internal primers. A minimum of 1 negative control was used for every 2 samples from patients with pneumonia; testing was conducted in a blinded manner.

Conclusions

In the study of 511 healthy Canadian controls, 12 (2.3%) exhibited a substantial titer of antibodies to Mimivirus. Patients with community-acquired pneumonia were positive more frequently than controls, as 36 (9.66%) were found positive (chi-square test, p < 0.01). Although the typical morphologic traits of Mimivirus make its confusion with ameba organelles unlikely (Figure), positive serum samples tested on noninfected intact amebas suspended in PBS by using the same migration inhibition factor protocol did not show any reactivity. Immunoelectron microscopic examination showed that antibodies of positive patients recognize mature Mimivirus particles specifically (Figure), whereas antibody fixation was not found in serum samples from 2 patients who were negative for Mimivirus (data not shown). We compared selected features of 14 patients with community-acquired pneumonia who had serologic evidence of infection with Mimivirus with those of 90 patients with community-acquired pneumonia who were seronegative for Mimivirus (Table). Only hospitalization from a nursing home (3/14 vs. 3/90) and rehospitalization after discharge (6/14 vs. 16/90) were significantly associated with Mimivirus antibodies (p < 0.05). Older age and diabetes mellitus were more common (both 6/14 versus 18/90) in patients with Mimivirus antibodies but not significantly so (p = 0.07). In patients with community-acquired pneumonia, more frequent rehospitalization after discharge in patients with serologic evidence of Mimivirus is likely explained by the poor efficacy of antimicrobial agents against viruses (15). Seropositive patients with community-acquired pneumonia were more likely to be admitted from a nursing home; this factor suggests that Mimivirus is a particularly good candidate as an etiologic agent of pneumonia acquired in institutions, as is L. pneumophila (16). The seroprevalence of Mimivirus...
patients was positive for Mimivirus (19.2%) of 26 ICU patients. None of the 50 control
bacteria tested on the same samples (4).
was significantly higher than that of ameba–associated
bacteria tested on the same samples (4).
Serologic evidence of infection was observed in 5
(19.2%) of 26 ICU patients. None of the 50 control
patients was positive for Mimivirus (p < 0.01). Mimivirus
DNA was detected in bronchoalveolar lavage specimen
from a 60-year-old comatose patient who had 2 episodes of
hospital-acquired pneumonia during hospitalization in
ICU. Mimivirus DNA was amplified from the second
episate sample only. The sequenced amplified fragment
was 100% homologous to the target DNA (GenBank
accession no. AY026860). No serum sample was available
from this patient. None of the DNA extracts from control
microorganism showed a positive PCR reaction. The finding
of Mimivirus DNA in the bronchoalveolar lavage speci-
mens from an ICU patient with nosocomial pneumonia
confirms that Mimivirus may reach the respiratory tract of
these patients. Because of the procedure used for suicide
PCR amplification, contamination appears highly unlikely.
In this patient, however, we cannot distinguish coloniza-
tion from infection, but this feature is common to most
microorganisms isolated from respiratory samples.
This high rate of seroconversion observed in patients
with pneumonia from our seroepidemiologic study sug-
ests that community-acquired pneumonia and hospital-
acquired pneumonia patients may have contact with
Mimivirus or a cross-reacting agent. As we do not report
direct evidence of infection by Mimivirus, these results
have to be interpreted with caution. Viruses usually have
a broad range of hosts, but the extraordinary size of the
Mimivirus genome (1.2 Mb), comparable to that of small
bacteria such as Mycoplasma (17), suggests a possible
adaptation to an extended range of hosts. We propose that
Mimivirus be tested as a possible novel human pathogen
among ameba-resisting microorganisms. These results are
preliminary, but raise the question of the pathogenic poten-
tial of the biggest identified virus to date. Mimivirus is an
agent easy to cultivate and is freely available from our lab-
atory on request to researchers working on pneumonia
who wish to introduce Mimivirus antigen in serologic tests
to confirm our results.

Dr. La Scola is professor of bacteriology at Université de la Méditerranée, Marseille, France. He is member of the Unité des Rickettssies (CNRS UMR6020, World Health Organization reference center for rickettssiae and rickettsial diseases). His fields of interest are the isolation and description of fastidious bacteria, including Coxiella, Rickettsia, Bartonella, Tropheryma, and ameba-associated bacteria.
