Abstract: The present paper introduces an approach to fault-tolerant reconfiguration for collaborating underwater robots. Fault-tolerant reconfiguration is obtained using the virtual actuator approach, Steffen (2005). The paper investigates properties of a centralised versus a decentralised implementation and assesses the capabilities under communication constraints between the individual robots. In the centralised case, each robot sends information related to its own status to a unique virtual actuator that computes the necessary reconfiguration. In the decentralised case, each robot is equipped with its own virtual actuator that is able to accommodate both local faults and faults within a collaborating unit. The paper discusses how this is done through exploiting structural information (e.g. thruster configuration) for each participant in the cooperation. A test scenario is presented as a case in which an underwater drill needs to be transported and positioned by three collaborating robots as part of an underwater autonomous operation.

Keywords: Collaborating robots, underwater robotics, fault tolerance control, actuator fault, reconfiguration, decentralised system.

1. INTRODUCTION

In recent years, the interest in collective robotics, which provides a new perspective based on cooperation between multiple robots, has grown significantly. The gain is that tasks can be performed in a more efficient and faster way compared to a single robot. In order to accomplish a specific goal, the interaction of robots working together has to be controlled through a centralised unit that takes over the individual local controllers to ensure optimal coordination and synchronization or through decentralised units to have low impact on communication.

In underwater environments, robots are subject to failures during their mission, so it is fundamental to examine the fault-tolerant aspects. Fault-tolerance is the property that enables the system to continue operating properly in case of non functional elements. A common source of failures are thrusters, due to their duct that can be easily blocked by seaweed or underwater life that can be sucked into the water flow.

The fault reconfiguration problem is a very active research topic, hence many different solutions have been proposed.

Yang et al. (1998, 1999) proposed a method for fault-tolerant reconfiguration where a failure of a thruster meant eliminating a thruster entirely from the equation to make the thruster configuration matrix invertible if sufficient redundancy remained in the system. The method considered complete thruster failures only. This problem was further addressed in Podder et al. (2000), where a weighted pseudo-inverse was introduced to optimize the thruster force distribution. The principle of reconfiguration through optimization of the control allocation gained interest over the last decade as the computational power increased, Indiveri and Parlangeli (2006). Sarkar et al. (2002) used the pseudo-inverse method to obtain fault accommodation, and it was noted that in case the faulty thruster configuration matrix does not contain full rank, the pseudo-inverse method cannot fulfill the reconfiguration goal. Omerdic and Roberts (2004) introduced a fault-tolerant control system using the pseudo-inverse method and to avoid infeasible solutions performed approximations through truncation and scaling to achieve an optimal feasible allocation. The method considered three types of faults: jammed propeller, heavily-jammed propeller and broken propeller. Zhu et al. (2008) employed a paradigm that considered faults to develop gradually and used fault magnitude estimation to compensate for thruster loss of efficiency. Sliding mode control was employed in Corradini et al. (2011), where the inherent robustness of the sliding mode controller was shown to be able to account for a range of thruster faults.

The present paper adopts a reconfiguration block (virtual actuator) to accommodate faults in a cluster of multiple underwater robots who collaborate to perform a task. A centralised and a decentralised implementation of a virtual actuator are presented. The former reconfigures the par-
Fig. 1. OpenROV, an open source underwater robot for educational purposes.

Participating robots which inform the unique virtual actuator about the status of their thrusters. The latter exploits structural information (e.g., where each robot is located in the cluster) to accommodate faults through a local virtual actuator. Choosing one implementation over the other is shown to depend on requirements and capabilities of the system (e.g., available communication channels). The faulty system together with the virtual actuator is shown to provide approximately the same output as the nominal system. It is demonstrated that almost the same path following capability is achieved in case of actuator faults, for both centralised and decentralised implementations, even if the control performance may be degraded (less agile as less thrust being available).

The paper is organised as follows. An example scenario is first introduced to motivate the concept of collaborating AUVs. AUV dynamics is then revisited and a conventional path control is selected as a standard controller for both centralised and individual AUV robot control. Handling of thruster faults is then discussed selecting a the virtual actuator approach for reconfiguration. Centralised and decentralised control and reconfiguration architectures are then analysed in view of the limited communication channel capabilities underwater. The main result is to show that an architecture for decentralised reconfiguration with limited inter-robot communication is feasible.

2. EXAMPLE SCENARIO

A test scenario has been created to expose the properties of a centralised versus decentralised control reconfiguration for collaborating underwater robots. The scenario has a background in a real life case where cracks occur in the structure of oil platforms due to severe weather, constant presence of extreme stresses and design flaws (e.g., the North Sea Oil platform, Siri). We focus on the transportation phase in which a drill is carried through a cut-out in the wall of the chamber in which repair service is needed. The drill is supported by three identical AUVs that are envisaged to have an attachment system that allows autonomous pick up and connection. Each robot has similar chassis and thruster configuration as an OpenROV (see Fig. 1). Each robot is equipped with three fixed direction (pitch) thrusters: two are mounted in parallel in a rear-facing configuration and one is transversal. This thruster configuration allows the robots to move in three dimensions but the single robot is under-actuated by having only 3 Degrees of Freedom (3DOF): surge, yaw and heave. It follows that the single robot lacks manoeuvrability in sway, roll and pitch.

If a tool needs to be carried to a desired location, the robots attach to the tool in defined positions. A configuration is shown in Fig. 2: the robots on the left, right and in back are referred to as S1, S2 and S3. When firmly engaged, the cluster has nine thrusters: five are "horizontal"; four are "vertical", seen in body coordinates. The robot that comprises the cluster of the tool and three robots is over-actuated and is able to move in 6DOF (see Table 1).

![Fig. 2. The cluster comprising three AUVs (S1, S2 and S3 are the robots on the left, right and back, respectively) attached to the drill. The earth reference frame is NED.](image)

Table 1. SNAME notation for marine crafts

| DOF                  | τ | ν | η |
|----------------------|---|---|---|
| Translation along x-axis (surge) | X | u | x |
| Translation along y-axis (sway)    | Y | v | y |
| Translation along z-axis (heave)   | Z | w | z |
| Rotation about x-axis (roll)       | K | p | φ |
| Rotation about y-axis (pitch)      | M | q | θ |
| Rotation about z-axis (yaw)        | N | r | ψ |

3. DYNAMICS

The dynamics of an individual robot follows its’ own equations of motion while free, but follows the dynamics of the cluster after attachment. Following Fossen (1994), the nonlinear equations of motion are, in body-fixed coordinates,

\[ \dot{\eta} = J(\eta)\nu \quad (1) \]

\[ M\ddot{\nu} + C(\nu)\nu + D(\nu)\nu + g(\eta) = \tau \quad (2) \]

where \( \eta = [x, y, z, \phi, \theta, \psi]^T \) refers to the position and orientation vector with coordinates in the North-East-Down (NED) earth-fixed frame. Orientation is represented by Euler angles: roll(\( \phi \)), pitch(\( \theta \)) and yaw(\( \psi \)).

\( \nu = [u, v, w, p, q, r]^T \) refers to the linear and angular velocity vector with coordinates in the body-fixed frame, which centre overlaps with the centre of gravity of the robot.

\( M \) is the inertia matrix which consists of the rigid-body mass matrix \( M_{RB} \) and the added mass matrix \( M_A \) due
to the inertia of the surrounding fluid and can be written as:

\[ M = M_{RB} + M_A \]  

(3)

\( C(\nu) \) is the matrix of Coriolis and centripetal terms (comprising added mass). Due to the low velocity at which the robots move, its effect on the dynamics is not worthy of being considered.

\( D(\nu) \) is the damping matrix that has the general form:

\[ D(\nu) = D_P(\nu) + D_V(\nu) + D_N(\nu), \]  

(4)

where \( D_P(\nu) \) is the damping due to the lost energy generated by surface waves (neglected for an AUV), \( D_V(\nu) \) and \( D_N(\nu) \) denote, respectively, the linear and nonlinear viscous damping caused by skin friction, vortex shedding and lift/drag effects, Fossen (2011).

\( g(\eta) \) is the vector of buoyant and gravitational forces (restoring forces) that, respectively, act through the centre of gravity and centre of buoyancy of the vehicle. Any rotations around the \( x \) or \( y \) axes are controlled by the hydrostatic forces of the vehicle.

\( J(\eta) \) is a transformation matrix which is related to the functions of Euler angles. It allows to change reference frames easily.

\[ \tau = [X, Y, Z, K, M, N]^T \] refers to forces and moments influencing the vehicle in the body-fixed frame used to achieve the desired motion.

\[ T \in \mathbb{R}^{d \times h} \] is the thrust configuration matrix that represents the position and orientation of each thruster in the system. \( T \) is defined as in Omerdic and Roberts (2004):

\[ T = \begin{bmatrix}
1e_x & 1e_y & 1e_z \\
\vdots & \vdots & \vdots \\
1e_x & 1e_y & 1e_z \\
(1 \times h)e_x & (1 \times h)e_y & (1 \times h)e_z
\end{bmatrix}\]  

(5)

d where \( d \) is the number of DOF, \( h \) is the number of thrusters, \( e = [e_x, e_y, e_z]^T \) is a unit vector that defines the orientation of a thruster and \( l = [l_x, l_y, l_z]^T \) is the position vector of a thruster with respect to the centre of gravity. \( \tau \) is obtained by exploiting \( T \) as shown in sub-section 4.3.

Table 1 shows the SNAME notation used in this paper. Appendix A provides matrices and parameters used to simulate the example scenario in section 2.

4. NOMINAL CONTROLLER ARCHITECTURE

The standard control structure is shown in Fig. 3. The output of the controller is the desired vector of forces and moments \( \tau_d \). Then, the control allocation block maps \( \tau_d \) into a vector control inputs \( u_c \) with as many elements as the actual number of thrusters. Control inputs are exploited to generates a vector of propulsion forces and moments \( \tau \) that is the input to the dynamics of the robot. The main objective of the control allocation is to ensure that the condition \( \tau_d = \tau \) is satisfied for all attainable \( \tau_d \), Omerdic and Roberts (2004).

![Fig. 3. The structure comprises a guidance block generating the path following, a control block that regulates the outputs to the desired values and a control allocator block for obtaining the vector of control input \( u_c \) to feed the plant.](image)

The system comprises an heading controller, a forward speed controller and a vertical controller. In the present paper, a 2D path control is used for simplification.

4.1 Heading controller

The controller acts on the vehicle in order to perform path tracking. In our scenario, the robot has to reach the given waypoints (provided by a human or another robot) in order to get as close as possible to the crack that must be prevented from extending further. It is supposed that an inspection robot has been sent before the transportation mission to identify the exact position of the crack.

The LOS guidance look ahead approach in Breivik and Fossen (2011) exploits the specified waypoints and the current positions in the earth fixed-frame in order to generate a reference \( \psi_r \). Afterwards, a low pass filter (LP) is used as a linear reference model for trajectory generation, defined as follows:

\[ \psi_d(s) = h_lP(s)\psi_r(s) \]  

(6)

A PID is used to compare the desired heading with the measured heading and to provide the yaw moment \( \tau_N \).

According to Fossen (2011), a feed-forward term \( \tau_{FF} \) should be determined such that perfect tracking during course-changing manoeuvres is obtained and it is implemented according to:

\[ \tau_{FF} = m_{PID}(\dot{\psi}_d + \frac{1}{T_{PID}}\tau_d), \]  

(7)

where \( m_{PID} = I_z - N_t \) and \( T_{PID} = -m_{PID}/N_t \).

The controller for the yaw moment \( \tau_N \) is defined as:

\[ \tau_N(s) = \tau_{FF}(s) - K_P(1 + T_Ds + \frac{1}{T_I}s)e_\psi(s), \]  

(8)

where \( e_\psi = \psi - \psi_d \) is the heading error, \( K_P > 0 \) is the PID proportional gain constant, \( T_D > 0 \) is the PID derivative time constant and \( T_I > 0 \) is the PID integral time constant.

When a decentralised controller is used, just one robot uses the PID control law previously explained. The other robots use a PID type control law with a droop switch around the integrator term in the PID that was active before physical connection of the robots was activated.

4.2 Control allocation

The input to the control allocation block is the vector of desired forces and moments \( \tau_d \), in which \( \tau_N \) is the controlled moment. The control allocator maps \( \tau_d \) into control inputs \( u_c \) that indicates the number of revolutions
that each thruster have to perform to achieve the desired forces and moments. It is defined as:

\[ u_c = K^{-1}T^t\tau_d = H\tau_d \quad (9) \]

\( T \) is the thrust configuration matrix defined in (5). \( K \in \mathbb{R}^{h \times h} \) is the force coefficient matrix:

\[ K = \begin{bmatrix} k_{11} & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & k_{hh} \end{bmatrix} \quad (10) \]

and:

\[ k_{jj} = \frac{T_{j_{\text{max}}}}{\rho D^4 |n_{j_{\text{max}}}| n_{j_{\text{max}}}} \quad j = 1, \ldots, h \quad (11) \]

where \( T_{j_{\text{max}}} \) is the maximum thrust provided, \( \rho \) is the water density, \( D \) is the propeller diameter, \( u_{j_{\text{max}}} = |n_{j_{\text{max}}}| n_{j_{\text{max}}} \) is the maximum thruster revolution (rpm) and \( h \) is the number of thrusters. The force coefficients are shown in Appendix A.3. A general overview of approaches used in thruster allocation is available in Johansen and Fossen (2013).

4.3 Computation of \( \tau \)

The vector of propulsion forces and moments \( \tau \) is defined as:

\[ \tau = TKu_c = Bu_c, \quad (12) \]

which is the input to the dynamics of the system.

Both centralised and decentralised controllers utilize the methods previously explained. Regarding the example scenario in section 2, the former considers all the thrusters of the system (i.e., nine) and the latter comprises the local thrusters of the individual robots (i.e., three).

5. RECONFIGURATION BY MEANS OF A VIRTUAL ACTUATOR

A fault causes a variation in the characteristics of a component such that the mode of operation or performance is changed in an undesired way. It has to be well distinguished from a failure that describes the inability of a system or a component to accomplish its function. A fault-tolerant control has to prevent a fault from causing a failure at the system level, Blanke et al. (2006).

The idea of reconfiguration is to build a unit for handling faults in the already existing control structure. The nominal controller is part of the reconfigured control. Thus, the controller that has been specifically designed to ensure the desired goals can still be used when needed. Finally, the purpose of the virtual actuator approach is to satisfy the fault hiding goal, which hides faults from the controller.

The virtual actuator replaces the effect of the faulty actuator by exploiting the other control inputs and it implicates the use of diverse I/O relations between the nominal controller and the plant.

In our scenario, a robot is most likely to have faults in actuators because of seaweed that can be sucked into the propeller’s duct or sea life that can be stuck into the water flow. An actuator fault changes or interrupts the performance of the system. An actuator fault changes or interrupts the performance of the system. A reconfiguration block constitutes the virtual actuator. Finally, \( \eta_{\text{ref}} \) is the reference signal. In the nominal case, the I/O relations are:

\[ u_c = u_f \quad (13) \]

\[ \eta_c = \eta_f \]

5.1 Centralised reconfiguration

A virtual actuator replaces the effect of the faulty actuator by exploiting the other control inputs and it implicates the use of diverse I/O relations between the nominal controller and the plant.

The virtual actuator is described as the following state space system, Steffen (2005):

\[ \dot{\nu}_\Delta = A\Delta \nu_\Delta + B_\Delta u_c, \quad \nu_\Delta(0) = \nu_{\Delta 0} \quad (14) \]

\[ u_f = C\nu_\Delta + D\Delta u_c \quad (15) \]

\[ \eta_c = C\nu_\Delta + \eta_f \quad (16) \]

with matrices:

\[ A_\Delta = A - B_f M_s \quad (17) \]

\[ B_\Delta = B - B_f N \quad (18) \]

\[ C_\Delta = M_s \quad (19) \]

\[ D_\Delta = N \quad (20) \]

\[ A = D \quad (21) \]

\( D \) is the damping matrix (see appendix A.2). \( A \) is the state matrix in which the restoring terms are not considered because of the stability of roll and pitch.

The matrix \( B_f \) maps the actuators’ inputs to the forces and moments to be used in the plant (see section 4.3).

The matrix \( B_f \) is constructed in case of a total fault (failure) in the \( j_{th} \) actuator. \( B_f \) is the same as \( B \) besides the \( j_{th} \) column that is set to zero.
The matrix $M_A$ has to be chosen so that the matrix $A - B_f M_A$ has eigenvalues with negative real parts in order to ensure the stability of the reconfigured closed loop system, Blanke et al. (2006). Thus, the pair $(A,B_f)$ is stabilizable.

The matrix $N$ can be chosen such as:

$$N = (B_f^T B_f)^{-1} B_f^T B$$

(22)

In order to ensure that the I/O relations are the same as (13), it is preferred to choose $N$ such as:

$$B_f \Delta = B - B_f N = 0$$

(23)

The condition (23) is satisfied when:

$$\text{rank } B_f = \text{rank } ([B,B_f])$$

(24)

In this case, the virtual actuator can be reduced to a static reconfiguration block:

$$u_f = Nu_c$$

(25)

$$\eta_f = \eta_c$$

(26)

and the matrix $N$ satisfies the property:

$$\sum_{j=1}^{h} \eta_{jw} = 1 \quad w = 1, \ldots, h$$

(27)

where $h$ is the number of thrusters. The property (27) produces $\sum u_f = \sum u_c$.

In the present paper, the measurement compensation in (16) is not considered since the controller should refer to the actual position and orientation.

A virtual actuator ensures the same (or approximately the same) performance to the system. By having a centralised controller and a virtual actuator, sharing information related to the status of each thruster is essential. The virtual actuator assumes that each thruster is completely functional unless it receives a message stating the contrary. The message consists in the contribution of the faulty robot to the matrix $N$ in (22). Afterwards, the virtual actuator asks for the contribution of the other robots participating in the cooperation. Once it collects their status, it constructs the $N$ matrix by joining the information, computes the new inputs $u_f$, and sends them to the robots.

**Algorithm Centralised reconfiguration**

**Given:**

- $o$ robots named $S_i$, $i = 1, \ldots, o$,
- $h_{Si}$ thrusters corresponding to robot $S_i$ and $h = \sum_{i=1}^{o} h_{Si}$,
- $f_{Si}$ actuator faults in robot $S_i$, $f_{Si} \leq h_{Si}$, $f = \sum_{i=1}^{o} f_{Si}$,
- matrices $B_{Si}$ and $B_{f_{Si}}$ defined in (12), a centralised controller (see section 4) and a virtual actuator located in one of the robots.

**Problem:**

Find $u_f$ defined in (25) such that the fault hiding goal (see subsection 5.1) and the performance indicator ($||\eta - \eta_f|| < 0$) are satisfied.

**Solution:**

- The faulty robot $S_i$ sends a triangular matrix $^tS_{f_{Si}}$ to the virtual actuator, obtained by the symmetric property of $S_{f_{Si}}$, which is a part of $N$:

$$S_{f_{Si}} = B_{f_{Si}}^T B_{Si}$$

(28)

$^tS_{f_{Si}}$ is sent in order to reduce the use of the communication channel.

- The virtual actuator asks the other robots $S_j$ ($j \neq i$) for their local contribution as in (28).

- The robots receiving the request construct their local contribution and send it to the virtual actuator. In case of a fault-free robot, the $B_{Si}$ has to be considered instead of $B_{f_{Si}}$.

- Once the virtual actuator obtains the information needed, it constructs the matrix $S$ as:

$$S = S_{f_{Si}} \circ \cdots \circ S_{f_{Si}}$$

(29)

where

- The virtual actuator computes the global matrix $B_f^T B_f$ by setting to zero the $f$ columns of $S$ corresponding to actuator faults.

- The virtual actuator computes $N$ as in (22) and finds $u_f$.

**Example scenario:** Fault on $S_1$’s vertical thruster

**Contribution from $S_1$:**

$$B_{f_{Si}}^T B_{Si} = ^tS_{f_{Si}} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ s_{Si} & 1 & 0 & 0 \\ s_{Si} & 1 & 1 & 0 \\ s_{Si} & 1 & 1 & 1 \end{bmatrix}$$

**Contribution from $S_2$:**

$$B_{f_{S2}}^T B_{S2} = ^tS_{S2} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ s_{S2} & s_{S2} & 0 & 0 \\ 1 & s_{S2} & 1 & 0 \\ 1 & s_{S2} & 1 & 1 \end{bmatrix}$$

**Contribution from $S_3$:**

$$B_{f_{S3}}^T B_{S3} = ^tS_{S3} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ s_{S3} & s_{S3} & 0 & 0 \\ s_{S3} & s_{S3} & s_{S3} & 0 \\ s_{S3} & s_{S3} & s_{S3} & s_{S3} \end{bmatrix}$$

Note that subscripts identify thrusters in the same robot. Finally, horizontal thrusters are omitted for clarity.

### 5.2 Decentralised reconfiguration

Communication is one of the most challenging aspects in underwater environments and, when it is possible, sharing modest information is a key rule. It might be possible to use a dedicated optical underwater communication system that could reach a bandwidth of 10 Mbit/s, Hanson and Radic (2008), over short ranges, but the bandwidth available off the shelf acoustic modems is in the 1-5 kBaund range. It follows that bandwidth is hence a serious concern.

To reduce even more the information to be shared to have a satisfactory fault-tolerant system, a decentralised controller and a decentralised virtual actuator are considered. It is assumed that robots store information related to force coefficients in (11), thruster configuration, position and orientation of each team member during the cooperation.

The inputs to the thrusters $u_{f_{Si}}$ are defined as:

$$u_{f_{Si}} = u_{f_{Si}} + N_{f_{Si}} u_c$$

(30)

Note that local thrusters are considered for its computation in order to satisfy the fault hiding goal. If there are no local faults, $u_{f_{Si}} = u_{c_{Si}}$. 

Note that subscripts identify thrusters in the same robot. Finally, horizontal thrusters are omitted for clarity.
$$N_{fs1} \in \mathbb{R}^{h_{Si} \times h}$$ comprises the additional contribution of robot $Si$ to the faulty robots. Each robot is able to construct its own copy of matrix $N$ as in (22) by considering the thrusters of the whole system. Finally, $N_{fs1}$ is obtained by selecting in $N$ the contribution to be provided by $Si$ in order to accommodate the fault.

$u_c$ refers to the nominal inputs of the whole system.

The decentralised virtual actuator decreases communication conspicuously, but the computational load on individual robots is increased.

**Algorithm Decentralised reconfiguration**

*Given:*

- $o$ robots named $Si$, $i = 1, \ldots, o$,
- $h_{Si}$ thrusters corresponding to robot $Si$,
- $f_{Si}$ actuator faults in robot $Si$,
- matrices $B_{Si}$ and $B_{fs_i}$ defined in (12) and subsection 5.1,
- a local controller (see section 4) and a local virtual actuator.

*Problem:*

Find $u_{fs_i}^f$ defined in (25) such that the fault hiding goal (see subsection 5.1) and the performance indicator ($\|\eta - \eta_f\| \simeq 0$) are satisfied.

*Solution:*

- The faulty robot $Si$ activates its local virtual actuator.
- $Si$ warns the other robots by communicating its actual status (i.e., fault identification).
- The robot $Sj$ ($i \neq j$) receives the message.
- $Sj$ computes $N_{fs_j}$ and finds $u_{fs_j}^f$ as in (30).

*Example scenario: Fault on $S1$'s vertical thruster*

**Inputs to be sent to $S1$'s thrusters:**

$$u_{fs1}^f = N_{S1} u_{cs1}$$

$$N_{S1} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix}$$

**Inputs to be sent to $S2$'s thrusters:**

$$u_{fs2}^f = u_{cs2} + N_{fs2} u_c$$

$$N_{fs2} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & n_{83} & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

**Inputs to be sent to $S3$'s thrusters:**

$$u_{fs3}^f = u_{cs3} + N_{fs3} u_c$$

$$N_{fs3} = \begin{bmatrix} 0 & 0 & n_{73} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & n_{83} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

Note that $n_{73}$ and $n_{83}$ have opposite sign to avoid the whole system to rotate about the y-axis (pitch).

Fig. 5. Fault handling capability of the centralised (in violet) versus decentralised (in green) control reconfiguration in case of a failure of robot $S1$. The robot follows a trajectory passing through ten waypoints (red circles). The annotations indicate the time elapsed to reach a waypoint.

6. RESULTS

The static reconfiguration block defined in (25, 26) is feasible up to two faults for horizontal thrusters and up to one fault for vertical thrusters, because the condition (24) is satisfied due to redundant thrusters with a similar effect as the faulty one. Horizontal and vertical faults can be handled simultaneously (e.g., a whole robot breaks down).

If a redundant thruster is not available for the reconfiguration, a dynamical block has to be used. This is the case for more than one fault in vertical thrusters.

A fault in the horizontal thruster of robot $S3$ causes loss of controllability since this is the only thruster in the system to provide heave (see Table 1).

If simultaneous vertical faults occurs in $S1$ and $S2$, the controllability requirement is not satisfied and the virtual actuator is not a solution to the problem.

Both the centralised and decentralised reconfigurations are able to accommodate the same combinations of faults, within the capabilities of thrust available in the two conditions. Since knowledge of the global system (i.e., thruster configuration and force coefficients) is exploited in both cases, performance requirements (i.e., $\|\eta - \eta_f\| \simeq 0$) can be made the same independently of the implementation.

Fig. 5 compares the performance of the centralised with the decentralised solutions when robot $S1$ fails. Differences in the path are due to the nominal controllers (see section 4).

Fig. 6 shows a comparison between the nominal force $X_n$ (torque $N_n$) and the faulty force $X_f$ (torque $N_f$) (see Table 1) in case of the total failure of robot $S1$ provided by the centralised system. Fig. 7 compares the nominal force $X_n$ (torque $N_n$) and the the faulty force $X_f$ (faulty torque $N_f$) (see Table 1) in case of the total failure of robot $S1$ provided by the decentralised system. Each change in force and torque corresponds to a new waypoint that has to be reached, so the robot adjusts according to it. Note that responses are time shifted due to the lower magnitude of total thrust available for propelling underwater robots.
Centralised and decentralised reconfiguration methods were compared in a scenario where three robots perform the task of carrying a drill. Using a conventional line of sight control for path following, the solution comprised path control and control allocator. Faults were handled by means of a virtual actuator. The virtual actuator was shown to provide approximately unchanged performance as the nominal case for the majority of thruster fault cases.

In the centralised approach, one of the robots acted as a leader and coordinated the actions of the team. While allowing for global optimization and completeness, the central unit could fail or communication channel difficulties could prevent timely sharing of information at the sampling frequency.

The decentralised version was based on every robot being autonomous and taking its own decisions. An algorithm was presented where only fault-status was communicated between robots.

As a future work, sensor faults and parameters uncertainty will be considered and a proof of equation (27) will be provided. Finally, a decentralised algorithm which does not rely on global structural information will be proposed. It should guarantee fault-handling capability even in case of flexible configurations among robots.

7. CONCLUSIONS

This paper focused on actuator faults as these are quite frequent in underwater missions, often due to seaweed, marine life or wires that block a thruster. Centralised and decentralised reconfiguration methods were compared in a scenario where three robots perform the task of carrying a drill. Using a conventional line of sight control for path following, the solution comprised path control and control allocator. Faults were handled by means of a virtual actuator. The virtual actuator was shown to provide approximately unchanged performance as the nominal case for the majority of thruster fault cases.

In the centralised approach, one of the robots acted as a leader and coordinated the actions of the team. While allowing for global optimization and completeness, the central unit could fail or communication channel difficulties could prevent timely sharing of information at the sampling frequency.

The decentralised version was based on every robot being autonomous and taking its own decisions. An algorithm was presented where only fault-status was communicated between robots.

As a future work, sensor faults and parameters uncertainty will be considered and a proof of equation (27) will be provided. Finally, a decentralised algorithm which does not rely on global structural information will be proposed. It should guarantee fault-handling capability even in case of flexible configurations among robots.

Appendix A. MATRICES AND PARAMETERS USED TO SIMULATE THE EXAMPLE SCENARIO

The inertia matrix $M$ and damping matrix $D$ are not full because the number of parameters can be severely reduced by exploiting body symmetry conditions. In particular, the configuration in which the robots assemble is symmetrical on the xy plane (bottom/top symmetry) and on the xz plane (port/starboard symmetry).

### A.1 Inertia Matrix:

$$
M_{RB} = \begin{bmatrix}
m & 0 & 0 & 0 & 0 & 0 \\
0 & m & 0 & -mx_y & 0 & 0 \\
0 & 0 & I_z & 0 & 0 & 0 \\
0 & 0 & -mx_y & I_y & 0 & 0 \\
0 & mx_y & 0 & 0 & 0 & I_z \\
\end{bmatrix}
$$

$$
M_A = -\begin{bmatrix}
X_u & 0 & 0 & 0 & 0 & 0 \\
0 & Y_v & 0 & 0 & Y_r & 0 \\
0 & 0 & Z_w & 0 & Z_q & 0 \\
0 & 0 & 0 & K_p & 0 & 0 \\
0 & 0 & M_v & 0 & M_q & 0 \\
0 & N_v & 0 & 0 & N_r & 0 \\
\end{bmatrix}
$$

(A.1) (A.2)

where $m$ is the total mass of the robot, $I_z$, $I_y$, and $I_z$ are the moments of inertia around $x_b$, $y_b$ and $z_b$ (body fixed coordinate system), respectively, and $x_g$ is the position of the centre of gravity around $x_b$.

### A.2 Damping Matrix:

$$
D_{V}(\nu) = -\begin{bmatrix}
X_{u}[|\nu|] & 0 & 0 & 0 & 0 & 0 \\
0 & Y_{v}[|\nu|] & 0 & 0 & Y_{r} & 0 \\
0 & 0 & Z_{w}[|\nu|] & 0 & Z_{q} & 0 \\
0 & 0 & 0 & K_{p} & 0 & 0 \\
0 & 0 & M_{v} & 0 & M_{q} & 0 \\
0 & N_{v} & 0 & 0 & N_{r} & 0 \\
\end{bmatrix}
$$

(A.3)

$$
D_{N}(\nu) = -\begin{bmatrix}
X_{u}[|\nu|] & 0 & 0 & 0 & 0 & 0 \\
0 & Y_{v}[|\nu|] & 0 & 0 & Y_{r} & 0 \\
0 & 0 & Z_{w}[|\nu|] & 0 & Z_{q} & 0 \\
0 & 0 & 0 & K_{p} & 0 & 0 \\
0 & 0 & M_{v} & 0 & M_{q} & 0 \\
0 & N_{v} & 0 & 0 & N_{r} & 0 \\
\end{bmatrix}
$$

(A.4)

### A.3 Force coefficients

Table A.5. Force coefficients for Graupner 2310.60 propellers

| Horizontal $k$ ($S1,S2$) | Horizontal $k$ ($S3$) | Vertical $k$ |
|--------------------------|-----------------------|--------------|
| 7.7                      | 26.1                  | 27.4         |

### A.4 Thrust configuration matrix

$$
T = \begin{bmatrix}
1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0.3 & 0.2 & -0.2 & 0 & 0 & 0 & 0 & 0 & 0 \\
\end{bmatrix}
$$

(A.5)

The first three columns refer to robot $S1$. The following three to $S2$ and the final three to $S3$. If robots are in a non-cluster configuration, each one has its $T$ reduced to a $3 \times 3$ matrix representing its own thruster configuration.
