ABSTRACT. The behavior at criticality of spatial SIR (susceptible/infected/recovered) epidemic models in dimensions two and three is investigated. In these models, finite populations of size \( N \) are situated at the vertices of the integer lattice, and infectious contacts are limited to individuals at the same or at neighboring sites. Susceptible individuals, once infected, remain contagious for one unit of time and then recover, after which they are immune to further infection. It is shown that the measure-valued processes associated with these epidemics, suitably scaled, converge, in the large-\( N \) limit, either to a standard Dawson-Watanabe process (super-Brownian motion) or to a Dawson-Watanabe process with location-dependent killing, depending on the size of the the initially infected set. A key element of the argument is a proof of Adler’s 1993 conjecture that the local time processes associated with branching random walks converge to the local time density process associated with the limiting super-Brownian motion.

1. INTRODUCTION

1.1. Spatial SIR epidemics. Simple spatial models of epidemics are known to exhibit critical thresholds in one dimension: Roughly, when the density of the initially infected set exceeds a certain level, the epidemic evolves in a markedly different fashion than its branching envelope. See Lalley (2007) for a precise statement, and Aldous (1997), Martin-Löf (1998), and Dolgoarshinnykh and Lalley (2006) for analogous results in the simpler setting of mean-field models. The main purpose of this article is to show that spatial SIR epidemics (SIR stands for susceptible/infected/recovered) in dimensions two and three also exhibit critical thresholds.

The epidemic models studied here take place in populations of size \( N \) located at the sites of the integer lattice \( \mathbb{Z}^d \) in \( d \) dimensions. Each of the \( N \) individuals at a site \( x \in \mathbb{Z}^d \) may at any time be either susceptible, infected, or recovered. Infected individuals remain infected for one unit of time, and then recover, after which they are immune to further infection. The rules of infections are as follows: at each time \( t = 0, 1, 2, \ldots \), for each pair \((i_x, s_y)\) of an infected individual located at \( x \) and a susceptible individual at \( y \), \( i_x \) infects \( s_y \) with probability \( p_N(x, y) \). We shall only consider the case where the transmission probabilities \( p_N(x, y) \) are spatially homogeneous, nearest-neighbor, and symmetric, and scale with the village size \( N \) in such a way that the expected number of infections by a contagious individual in an otherwise healthy population is 1 (so that the epidemic is critical), that is,

Assumption 1. \( p_N(x; y) = 1/[(2d + 1)N] \) if \( |y - x| \leq 1 \); and = 0 otherwise.

Our main result, Theorem 2 below, asserts that under suitable hypotheses on the initial configurations of infected individuals, the critical spatial SIR\(-d\) epidemic can be rescaled so as to converge
to a Dawson-Watanabe measure-valued diffusion in both $d = 2$ and $d = 3$. Depending on the size of the initially infected set, the limiting Dawson-Watanabe process has either a positive killing rate or no killing at all. The analogous result for $d = 1$ was proved in Lalley (2007), using the fact that one-dimensional super-Brownian motion (the Dawson-Watanabe process with no killing) has sample paths in the space of absolutely continuous measures. In higher dimensions this is no longer true, so a different strategy is needed.

1.2. Branching envelope of a spatial epidemic. The spatial SIR epidemic in $d$ dimensions is naturally coupled with a nearest neighbor branching random walk on the integer lattice $\mathbb{Z}^d$; this branching random walk is often referred to as the branching envelope of the epidemic. Particles of this branching random walk represent infection attempts in the coupled epidemic, some of which may fail to be realized in the epidemic because the targets of the attempts are either recovered or are targets of other simultaneous infection attempts. The branching envelope evolves as follows: Any particle located at site $x$ at time $t$ lives for one unit of time and then reproduces, placing random numbers $\xi_y$ of offspring at the sites $y$ such that $|y - x| \leq 1$. The random variables $\xi_y$ are i.i.d., with Binomial$(N, 1/[(2d + 1)N])$ distributions. Denote this reproduction rule by $R_N$, and denote by $R_\infty$ the corresponding offspring law in which the Binomial distribution is replaced by the Poisson distribution with mean $1/(2d + 1)$. Since offspring are placed independently at each of the $2d + 1$ nearest neighbors, the expected total number of offspring of a particle is 1, i.e. the branching random walk is critical. Moreover, under either reproduction rule $R_N$ or $R_\infty$, particle motion is governed by the law of the simple nearest neighbor random walk on $\mathbb{Z}^d$ (with holding probability $1/(2d + 1)$): In particular, given that a particle at site $x$ has $k$ offspring, each of these offspring independently chooses a neighboring site $y$ according to the law

\[ P_1(x, y) = 1/(2d + 1) \quad \text{for} \quad |y - x| \leq 1. \]

Note that the covariance matrix of the increment has determinant $\sigma^{2d}$, where $\sigma^2$ is the variance parameter of the jump distribution, defined by

\[ \sigma^2 := \left( \frac{2}{2d + 1} \right). \]

The spatial SIR-$d$ epidemic can be constructed together with its branching envelope on a common probability space in such a way that the branching envelope dominates the epidemic, that is, for each time $n$ and each site $x$ the number of infected individuals at site $x$ at time $n$ is no larger than the number of particles in the branching envelope. The construction, in brief, is as follows (see Lalley (2007)): Particles of the branching random walk will be colored either red or blue according to whether or not they represent infections that actually take place, with red particles representing actual infections. Initially, all particles are red. At each time $t = 0, 1, 2, \ldots$, particles produce offspring at the same or neighboring sites according to the law $R_N$ described above. Offspring of blue particles are always blue, but offspring of red particles may be either red or blue, with the choices made according to the following procedure: All offspring of red particles at a location $y$ choose numbers $j \in [N] := \{1, 2, \ldots, N\}$ at random, independently of all other particles. If a particle chooses a number $j$ that was previously chosen by a particle of an earlier generation at the same site $y$, then it is assigned color blue. If $k > 1$ offspring of red particles choose the same number

\[1\text{Throughout the paper, the term simple random walk will mean simple random walk with holding probability } 1/(2d + 1).\]
at the same time, and if \( j \) was not chosen in an earlier generation, then 1 of the particles is assigned color red, while the remaining \( k - 1 \) are assigned color blue. Under this rule, the subpopulation of red particles evolves as an SIR\(-d\) epidemic.

It is apparent that when the numbers of infected and recovered individuals at a site and its nearest neighbors are small compared to \( N \), then blue particles will be produced only infrequently, and so the epidemic process will closely track its branching envelope. Only when the sizes of the recovered and infected sets reach certain critical thresholds will blue particles start to be produced in large numbers, at which point the epidemic will begin to diverge significantly from the branching envelope. Our main result, Theorem 2 below, implies that the critical threshold for the number of initially infected individuals is on the order \( N^{1/(3-d/2)} \).

The SIR\(-d\) epidemic is related to its branching envelope in a second — and for our purposes more important — way. The law of the epidemic, as a probability measure on the space of possible population trajectories, is absolutely continuous relative to the law of its branching envelope. The likelihood ratio can be expressed as a product over time and space, with each site/neighbor/generation contributing a factor (see \S 3.3 below). Each such factor involves the total occupation time \( R_N^t(x) \) of the site, that is, the sum of the number of particles at site \( x \) over all times prior to \( n \). Thus, the asymptotic behavior of the occupation time statistics for branching random walks will play a central role in the analysis of the large-\( N \) behavior of the SIR\(-d\) epidemic.

1.3. Watanabe’s Theorem. A fundamental theorem of Watanabe (1968) asserts that, under suitable rescaling (the Feller scaling) the measure-valued processes naturally associated with critical branching random walks converge to a limit, the standard Dawson-Watanabe process, also known as super-Brownian motion.

**Definition 1.** The Feller-Watanabe scaling operator \( F_k \) scales mass by \( 1/k \) and space by \( 1/\sqrt{k} \), that is, for any finite Borel measure \( \mu(dx) \) on \( \mathbb{R}^d \) and any test function \( \psi \in C^\infty_c(\mathbb{R}^d) \),

\[
(\psi, F_k \mu) = k^{-1} \int \psi(\sqrt{k}x) \mu(dx).
\]

**Watanabe’s Theorem.** Fix \( N \), and for each \( k = 1, 2, \ldots \), let \( X^k_t \) be a branching random walk with offspring distribution \( R_N \) and initial particle configuration \( X^k_0 \). (In particular, \( X^k_t(x) \) denotes the number of particles at site \( x \in \mathbb{Z}^d \) in generation \([t]\), and \( X^k_t \) is the corresponding counting measure.) If the initial mass distributions converge, after rescaling, as \( k \to \infty \), that is, if

\[
F_k X^k_0 \Rightarrow \mu = X_0
\]

for some finite Borel measure \( \mu \) on \( \mathbb{R}^d \), then the rescaled measure-valued processes \( (F_k X^k)_kt \) converge in law as \( k \to \infty \):

\[
(F_k X^k)_kt \Rightarrow X_t,
\]

where \( \Rightarrow \) represents the weak convergence relative to the Skorokhod topology on \( D([0, \infty); M_F(\mathbb{R}^d)) \). The limit is the standard Dawson-Watanabe process \( X_t \) (super-Brownian motion) with variance parameter \( \sigma^2 \) (equivalently, standard super-Brownian motion run at speed \( \sigma \)).

See Etheridge (2000) for an in-depth study of the Dawson-Watanabe process and a detailed proof of Watanabe’s Theorem. Because the process \( X_t \) has continuous sample paths in the space of finite
Borel measures, it follows routinely from Watanabe’s theorem that the occupation measures for branching random walks converge to those of super-Brownian motion:

**Lemma 1.** The following joint convergence holds:

\[
\left( (F_k X^k)_{kt}, \left( \int_0^t (F_k X^k)_{ks} \, ds \right) \right) \Rightarrow \left( X_t, \int_0^t X_s \, ds \right),
\]

where \( \Rightarrow \) represents weak convergence relative to the Skorokhod topology on \( D([0, \infty); M_F(\mathbb{R}^d))^2 \).

**Proof.** The Dawson-Watanabe process \( X_t \) has continuous sample paths in \( D([0, \infty); M_F(\mathbb{R}^d)) \), see, e.g., Proposition 2.15 in Etheridge (2000). The functional \( (X_t) \mapsto (\int_0^t X_s \, ds) \) is continuous relative to the Skorokhod topology on the subspace of continuous measure-valued processes, so the result follows from Watanabe’s theorem and the continuous mapping principle.

**1.4. Local times of critical branching random walks.** In dimension \( d = 1 \) the super-Brownian motion has sample paths in the space of absolutely continuous measures, that is, for each \( t > 0 \) the random measure \( X_t \) is absolutely continuous relative to Lebesgue measure (Konno and Shiga (1988), Reimers (1989)). Moreover, the Radon-Nikodym derivative \( X(t, x) \) is jointly continuous in \( t, x \) (for \( t > 0 \)). It is shown in Lalley (2007) that if a sequence of branching random walks satisfy the assumptions in Watanabe’s Theorem, then the density processes associated with those branching random walks, under some smoothness assumptions on the initial configurations and after suitable scaling, converge to the density process of the limiting super-Brownian motion. In dimensions \( d \geq 2 \) the measure \( X_t \) is almost surely singular (Dawson and Hochberg (1979)). Therefore, one cannot expect the convergence of density processes as in Lalley (2007). We shall prove, however, that the occupation measures of critical branching random walks have discrete densities that converge weakly — see Theorem \( \square \) below. The limit process is the local time process associated with the occupation measure

\[
L_t := \int_0^t X_s \, ds
\]

of the super-Brownian motion. In dimensions \( d = 2, 3 \), the random measure \( L_t \) is, for each \( t > 0 \), absolutely continuous, despite the fact that \( X_t \) is singular — see Sugitani (1989), Iscoe (1986) and Fleischmann (1988). Moreover, under suitable hypotheses on the initial condition \( X_0 \), the density process \( L_t(x) \) is jointly continuous for \( t > 0 \) and \( x \in \mathbb{R}^d \); This is the content of Sugitani’s theorem. For the reader’s convenience, we state Sugitani’s Theorem precisely here. For \( t > 0 \) and \( x \in \mathbb{R}^d \), set

\[
q_t(x) = \int_0^t \phi_s(x) \, ds,
\]

where \( \phi_t(x) = \frac{e^{-|x|^2/2t}}{(2\pi t)^{d/2}} \) is the usual heat kernel.

**Sugitani’s Theorem.** Assume that \( d = 2 \) or \( 3 \), and that the initial configuration \( \mu := X_0 \) of the super-Brownian motion \( X_t \) is such that the convolution

\[
(q_t \ast \mu)(x) \text{ is jointly continuous in } t \geq 0 \text{ and } x \in \mathbb{R}^d.
\]

Then for each \( t \geq 0 \) the occupation measure \( L_t \) is absolutely continuous, and there is a jointly continuous version \( L_t(x) \) of the density process.
We call \((L_t(x))_{t \geq 0, x \in \mathbb{R}^d}\) the local time density process associated with the super-Brownian motion. In view of Watanabe’s and Sugitani’s theorems, it is natural to conjecture (see Remark 1 below) that the local time density processes of branching random walks, suitably scaled, converge to the local time density process of the super-Brownian motion. Theorem 1 below asserts that this conjecture is true. Let \(X^k\) be a sequence of branching random walks on \(\mathbb{Z}^d\). Write

\[
X^k_t(x) := \# \text{ particles at } x \text{ at time } t, \quad \text{and} \quad R^k_n(x) := \sum_{i<n} X^k_i(x).
\]

(We use the notation \(R^k_n\) instead of \(L^k_n\) because in the corresponding spatial epidemic model, the quantity \(R^k_n(x)\) represents the number of recovered individuals at site \(x\) and time \(n\).) Denote by \(P_n = (P_n(x,y))_{x,y \in \mathbb{Z}^d} = (P_n(y-x))_{x,y \in \mathbb{Z}^d}\) the transition probability kernel of the simple random walk on \(\mathbb{Z}^d\), that is, \(P_n = P \ast P^{n-1}\) is the \(n\)th convolution power of the one-step transition probability kernel given by (1). Let \(G_n(x,y)\) be the associated Green’s function:

\[
G_n(x) := \sum_{i<n} P_i(x).
\]

For any finite measure \(\mu\) on \(\mathbb{Z}^d\) with finite support, set

\[
(\mu G_n)(x) := (\mu \ast G_n)(x) = \sum_y \mu(y)G_n(x-y),
\]

and denote by \(\mu G_t(y)\) the continuous extension to \([0, \infty) \times \mathbb{R}^d\) by linear interpolation.

**Theorem 1.** Assume that \(d = 2\) or \(d = 3\). For each \(k = 1, 2, \ldots\), let \(X^k_t\) be a branching random walk whose offspring distribution is Poisson with mean 1. Assume that the initial configurations \(\mu^k := X^k_0\) satisfy hypothesis (4) of Watanabe’s theorem, where the limit measure \(\mu\) has compact support and satisfies the hypothesis (6) of Sugitani’s theorem. Assume further that

\[
\frac{\mu^k G_{kt} \sqrt{kx}}{k^{d-2}/2} \Longrightarrow \left(\frac{q\sigma_t \ast \mu}{\sigma^2}\right)(x),
\]

where \(\Rightarrow\) indicates weak convergence in the topology of \(D([0, \infty), C_k(\mathbb{R}^d))\). Then as \(k \to \infty\),

\[
\frac{R^k_{kt} \sqrt{kx}}{k^{d-2}/2} \Longrightarrow L_t(x),
\]

where \(L_t(x)\) is the local time density process associated with the super-Brownian motion with variance parameter \(\sigma^2\) started in the initial configuration \(X_0 = \mu\).

Theorem 1 will be proved in §2.

**Remark 1.** The analogous result for critical branching Brownian motions was conjectured by Adler (1993), who proved the marginal convergence for any fixed \(t\) and \(x\).

**Remark 2.** The assumption that the offspring distribution is Poisson with mean 1 can be relaxed. All that is really needed is that the offspring distribution has an exponentially decaying tail. See Remark 7.
Remark 3. The hypothesis (4) does not by itself imply (9), even if the limit measure \( \mu \) satisfies the hypothesis (6) of Sugitani’s theorem. Sufficient conditions for (9) are given in Proposition 1 below. In particular, in dimension 2, if (4) holds and the maximal number of particles on a single site is bounded in \( k \), then (9) is satisfied.

Remark 4. Let \( X_t \) be super-Brownian motion in dimension \( d = 2 \). For each \( t > 0 \) the random measure \( X_t \) is singular, so by Fubini’s theorem, for almost every point \( x \in \mathbb{R}^2 \) the set of times \( t > 0 \) such that \( x \) is a point of density of \( X_t \) has Lebesgue measure 0. Under hypothesis (9) we can make an analogous quantitative statement for branching random walk: For any fixed \( x \in \mathbb{Z}^2 \) and all \( t > 0 \),

\[
E \left[ \frac{[kt]}{m=1} I_{X_m^k(x) > 0} \right] = O(k/\log k).
\]

Proof. By Proposition 35 in Lalley and Zheng (2007), there exists \( \delta > 0 \) such that for all \( k \) and \( m \) sufficiently large,

\[
E \left[ X_m^k(x) | X_m^k(x) > 0 \right] \geq \delta \log m.
\]

But hypothesis (9) implies that

\[
ER_k^{X_m^k(x)} = (\mu^k G^k_t)(x) = O(k),
\]

and

\[
ER_k^{X_m^k(x)} = \sum_{m<k} E X_m^k(x) = \sum_{m<k} E \left[ X_m^k(x) | X_m^k(x) > 0 \right] \cdot P \left[ X_m^k(x) > 0 \right] .
\]

1.5. Scaling limit of spatial SIR epidemic. Before stating our result, we first recall the definition of Dawson-Watanabe processes with variable-rate killing. The Dawson-Watanabe process \( X_t \) with killing rate \( \theta = \theta(x, t, \omega) \) (assumed to be progressively measurable and jointly continuous in \( (t, x) \)) and variance parameter \( \sigma^2 \) can be characterized by a martingale problem (Dawson and Perkins (1999), §6.2): For any test function \( \psi \in C_\infty^2(\mathbb{R}^d) \),

\[
\langle X_t, \psi \rangle - \langle X_0, \psi \rangle = \frac{\sigma^2}{2} \int_0^t \langle X_s, \Delta \psi \rangle \, ds + \int_0^t \langle X_s, \theta(\cdot, s) \psi \rangle \, ds
\]

is a martingale with the same quadratic variation as for super-Brownian motion with variance parameter \( \sigma^2 \). The Dawson-Watanabe process with killing rate 0 (which we sometimes refer to as the standard Dawson-Watanabe process) is super-Brownian motion. Existence and distributional uniqueness of Dawson-Watanabe processes in general is asserted in Dawson and Perkins (1999) and proved, in various cases, in Dawson (1978) and Evans and Perkins (1995). It is also proved in these articles that the law of a Dawson-Watanabe process with killing on a finite time interval is absolutely continuous with respect to that of a standard Dawson-Watanabe process with the same variance parameter, and that the likelihood ratio (Radon-Nikodym derivative) is (Dawson and Perkins (1999))

\[
\exp \left\{ - \int \theta(t, x) \, dM(t, x) - \frac{1}{2} \int \langle X_t, \theta(t, \cdot)^2 \rangle \, dt \right\} ,
\]

where \( \theta \) is the killing rate and \( M \) is the measure of jumps.
where \(dM(t, x)\) is the orthogonal martingale measure attached to the standard Dawson-Watanabe process (see Walsh (1986)). Absolute continuity implies that sample path properties are inherited: In particular, when \(d = 2, 3\), if \(X_t\) is a Dawson-Watanabe process with killing, then almost surely its occupation time process \(L_t\) is absolutely continuous, with local time density \(L_t(x)\) jointly continuous in \(x\) and \(t\).

It can be shown that in all dimensions \(d\), the critical threshold is still Perkins for pointing this out to us. It can be shown that in all dimensions \(d\), the critical threshold is still Perkins for pointing this out to us. It can be shown that in all dimensions \(d\), the critical threshold is still Perkins for pointing this out to us.

It is shown in [Lalley (2007)] that for the SIR-1 epidemic in \(\mathbb{Z}\) with village size \(N\), the particle density processes, suitably rescaled, converge as \(N \to \infty\) to the density process of a standard Dawson-Watanabe process or a Dawson-Watanabe process with location-dependent killing, depending on whether the total number of initial infections is below a critical threshold or not. In dimensions \(d \geq 2\), one cannot expect such a result to hold, because the Dawson-Watanabe process is almost surely singular with respect to the Lebesgue measure and therefore has no associated density process. However, as measure-valued processes, the SIR-\(d\) \((d = 2, 3)\) epidemics, under suitable scaling, do converge, as the next theorem asserts. For the SIR-\(d\) model with village size \(N\), define

\[
X_i^N(x) : = \# \text{infected particles at } x \text{ at time } i; \\
R_i^N(x) : = \# \text{recovered particles at } x \text{ at time } n = \sum_{i<n} X_i^N(x).
\]

**Theorem 2.** Assume that \(d = 2\) or \(3\), and suppose that for some \(\alpha \leq 1/(3 - d/2)\) the initial configurations \(\mu^N \equiv X_0^N\) are such that

\[
\mathcal{F}_{\alpha^N} \mu^N \Rightarrow \mu \text{ with compact support, and}
\]

\[
((\mu^N \sigma_0^N)(\sqrt{\alpha^N})/N^{\alpha(2-d)/2}) \Rightarrow [(q_{\alpha^N} \ast \mu)/\sigma^2](x) \in C(\mathbb{R}^{1+d})
\]

where the second convergence is in \(D([0, \infty); C_b(\mathbb{R}^d))\). Then

\[
(\mathcal{F}_{\alpha^N}X^N)_{\alpha^N} \Rightarrow X_t
\]

where the limit process \(X_t\) is a Dawson-Watanabe process with initial configuration \(X_0 = \mu\), variance parameter \(\sigma^2\), and killing rate \(\theta\). The killing rate depends on the value of \(\alpha\) as follows:

(i) if \(\alpha < 1/(3 - d/2)\), then \(\theta \equiv 0\); and

(ii) if \(\alpha = 1/(3 - d/2)\), then \(\theta = L_t(x)\),

where \(L_t(x)\) is the local time density of the process \(X_t\). The convergence \(\Rightarrow\) in (16) is weak convergence relative to the Skorokhod topology on \(D([0, \infty); M_F(\mathbb{R}^d))\).

**Theorem 2** will be proved in §3.

**Remark 5.** Theorem 2 asserts that there is a critical threshold for the SIR-\(d\) epidemic in dimensions \(d = 2, 3\). Below the threshold (when the sizes of the initially infected populations are \(\ll N^{\alpha_s}\), where \(\alpha_s = 1/(3 - d/2)\) is the critical exponent) the effect of finite population size is not felt, and the epidemic looks much like its branching envelope. At the critical threshold, the finite-population effects begin to show, and the epidemic now looks like a branching random walk with location-dependent killing.

**Remark 6.** The critical behavior of the SIR-\(d\) epidemics in dimensions \(d \geq 4\) is considerably simpler. It can be shown that in all dimensions \(d \geq 5\), the critical threshold is \(\alpha = 1\); in the four dimensional case, the critical threshold is still \(\alpha = 1\) but there will be logarithmic corrections – we thank Ed Perkins for pointing this out to us.
1.6. Notational conventions. Since the proof of Theorem 2 is based on likelihood ratio calculations, we shall, at the risk of minor confusion, use the same letters $X$ and $R$, with subscripts and/or superscripts, to denote particle counts and occupation counts for both branching random walks and the SIR-$d$ epidemic processes (see equations (12) and (13)) and for their continuous limits. Throughout the paper, we use the notation $f \asymp g$ to mean that the ratio $f/g$ remains bounded away from 0 and $\infty$. Also, $C, C_1,$ etc. denote generic constants whose values may change from line to line. The notation $\delta_x(\cdot)$ is reserved for the Kronecker delta function. The notation $Y_n = o_P(f(n))$ means that $Y_n/f(n) \to 0$ in probability; and $Y_n = O_P(f(n))$ means that the sequence $|Y_n|/f(n)$ is tight. Finally, we use a “local scoping rule” for notation: Any notation introduced in a proof is local to the proof, unless otherwise indicated.

2. Local time for branching random walk in $d = 2, 3$

2.1. Estimates on transition probabilities. Recall that $P_n = (P_n(x - y))$ is the $n$-step transition probability kernel for the simple random walk on $\mathbb{Z}^d$ (with holding parameter $1/(2d + 1)$). For critical branching random walk, $P_n(x, y)$ is the expected number of particles at site $y$ at time $n$ given that the branching random walk is initiated by a single particle at site $x$. For this reason, sharp estimates on these transition probabilities will be of crucial importance in the proof of Theorem 1.

We collect several useful estimates here. As the proofs are somewhat technical, we relegate them to the Appendix (section 4 below). Write

$$\Phi_n(x, y) = \phi_n(x) + \phi_n(y)$$

where

$$\phi_n(x) = \frac{1}{(2\pi n)^{d/2}} \exp\left(-\frac{|x|^2}{2n}\right)$$

is the Gauss kernel in $\mathbb{R}^d$. The first two results relate transition probabilities to the Gauss kernel.

**Lemma 2.** For all sufficiently small $\beta > 0$ there exists constant $C = C(\beta) > 0$ such that for all integers $m, n \geq 1$ and all $x \in \mathbb{Z}^d$,

\begin{align}
P_n(x) &\leq C\phi_n(\beta x) \quad \text{and} \\
(P_m \ast \phi_n)(\beta x) &\leq C\phi_{m+n}(\beta x/2).
\end{align}

Furthermore, for each $A > 0$ and each $T > 0$ there exists $C = C(A, T) > 0$ such that for all $k$ sufficiently large and all $|x| \leq A\sqrt{k}$,

$$\sum_{n \leq kT} \phi_n(\beta x) \leq C \sum_{n \leq kT} P_n(x).$$

**Lemma 3.** For all sufficiently small $\beta > 0$ there exists constant $C = C(\beta) > 0$ such that for all integers $n \geq 1$ and all $x, y \in \mathbb{Z}^d$,

$$|P_n(x) - P_n(y)| \leq C \left(\frac{|x - y|}{\sqrt{n}} \wedge 1\right) \cdot \Phi_n(\beta x, \beta y).$$

In particular, for all $\gamma \leq 1$,

$$|P_n(x) - P_n(y)| \leq C \left(\frac{|x - y|}{\sqrt{n}}\right)^\gamma \cdot \Phi_n(\beta x, \beta y).$$

Our arguments will also require the following estimates on the discretized Green kernel.
Lemma 4. For each $\gamma \in (0, 2-d/2)$, $\beta > 0, h \geq 1, n \in \mathbb{N},$ and $x, y \in \mathbb{Z}^d$, define
\begin{equation}
F_{n,h}(x, y; \beta) = F_{n,h;\gamma}(x, y; \beta) = \sum_{|\rho| h} \sum_{l < n} \frac{1}{l^{d/2}} \phi_l(\beta(x + \rho), \beta(y + \rho)),
\end{equation}
where the first summation is over $\rho \in \mathbb{Z}^d$ with $|\rho| < h$. Then there exists $C = C(\gamma, \beta, d) < \infty$ such that for all $n \in \mathbb{N}, h_1, h_2 \geq 1,$ and all $x, y \in \mathbb{Z}^d$, the following inequalities hold:
\begin{equation}
F_{n,h_1}(x, y; \beta) \cdot F_{n,h_2}(x, y; \beta) \leq Cn^{2-(d+\gamma)/2} F_{n,h_1+h_2-1}(x, y; \beta),
\end{equation}
and
\begin{align}
&\sum_{i < n} \sum_{z} P_i(z) \cdot [F_{n-i,h_1}(x - z, y - z; \beta) \cdot F_{n-i,h_2}(x - z, y - z; \beta)] \\
&\leq Cn^{2-(d+2\gamma)/2} \sum_{|\rho| h_1+h_2-1} \sum_{l < n} \phi_l(\beta(x + \rho), \beta(y + \rho)/2) \\
&\leq Cn^{2-(d+\gamma)/2} F_{n,h_1+h_2-1}(x, y; \beta/2).
\end{align}
(Note that in the last term the $\beta$ parameter is changed to $\beta/2$.)

Lemma 5. For each $\beta > 0, h \geq 1, m, n \in \mathbb{N},$ and $x \in \mathbb{Z}^d$, define
\begin{equation}
J_{m,n,h}(x; \beta) = \sum_{|\rho|, h} \sum_{m \leq l < m+n} \phi_l(\beta(x + \rho)),
\end{equation}
where the first summation is over $\rho \in \mathbb{Z}^d$ with $|\rho| < h$. Then there exists $C = C(\beta) > 0$ such that for all $m, n \in \mathbb{N}, h_1, h_2 \geq 1,$ and all $x \in \mathbb{Z}^d$, the following inequalities holds:
\begin{equation}
J_{m,n,h_1}(x; \beta) \cdot J_{m,n,h_2}(x; \beta) \leq Cn^{2-d/2} J_{m,n,h_1+h_2-1}(x; \beta),
\end{equation}
and
\begin{align}
&\sum_{i < n} \sum_{z} P_i(z) \cdot [J_{m-n+i,h_1}(x - z; \beta) \cdot J_{m-n+i,h_2}(x - z; \beta)] \\
&\leq Cn^{2-d/2} J_{m,n,h_1+h_2-1}(x; \beta/2).
\end{align}

2.2. Proof of Theorem. For notational ease, we omit the superscript $k$ in the arguments below: thus, we write $X_n(x)$ instead of $X_n^k(x)$, and $R_n(x)$ instead of $R_n^k(x)$. To prove the theorem it suffices to prove that (1) the sequence of random processes $(R_{kt}(\sqrt{k}x)/k^{d/2})$ is tight in the space $D([0, \infty); C_b(\mathbb{R}^d));$ and (2) that the only possible weak limit is the local time density process $L_t(x)$. The second of these is easy, given Lemma. This implies that for any test function $\psi \in C_c(\mathbb{R}^d)$,
\begin{align}
\frac{1}{k^2} \sum_x R_{kt}(\sqrt{k}x)\psi(x) \\
= \frac{1}{k} \sum_{i \leq kt} \sum_x X_i(\sqrt{k}x)\psi(x)/k \\
\rightarrow \mathcal{L} \int_0^t X_s(\psi) \, ds,
\end{align}
where \((X_t)\) is the super-Brownian motion started in configuration \(X_0 = \mu\), run at speed \(\sigma\). Hence, any weak limit of the sequence \((R_{kt}(\sqrt{k}x)/k^{2-d/2})\) must be a density of the occupation measure for super-Brownian motion. On the other hand, by Remark 3 and Sugitani’s Theorem,

\[
\int_0^t X_s(\psi) \, ds = \int_x L_t(x) \psi(x) \, dx.
\]

It follows that \(L_t(x)\) is the only possible weak limit.

Thus, to prove Theorem 1 it suffices to prove that the sequence \((R_{kt}(\sqrt{k}x)/k^{2-d/2})\) is tight in the space \(D([0, \infty); C_b(\mathbb{R}^d))\). In view of hypothesis (6), it is enough to prove the tightness of the re-centered sequence

\[(28) \quad Y_k(t, x) := \left( R_{kt}(\sqrt{k}x) - (\mu^k G_{kt})(\sqrt{k}x) \right) / k^{2-d/2}. \]

This we will accomplish by verifying a form of the Kolmogorov-Centsov criterion. According to this criterion, to prove tightness it suffices to prove that for each compact subset \(K\) of \([0, \infty) \times \mathbb{R}^d\) there exist constants \(C < \infty, \alpha > 0, \) and \(\delta > d + 1\) such that for all pairs \((s, a), (t, b) \in K\),

\[
(29) \quad E|Y_k(t, a) - Y_k(t, b)|^\alpha \leq C|a - b|^\delta \quad \text{and} \quad (30) \quad E|Y_k(t, a) - Y_k(s, a)|^\alpha \leq C|t - s|^\delta.
\]

The trick is to not work with moments directly, but instead, following the strategy of Sugitani (1989), to work with cumulants:

**Lemma 6** (Lemma 3.1 in Sugitani (1989)). Let \(X\) be a random variable with moment generating function \(E \exp(\theta X) = \exp(\sum_{n=1}^{\infty} \theta^n a_n)\). If for some integer \(N\) there exists \(r, b > 0\) such that

\[|a_n| \leq br^n, \text{ for } n \leq 2N,\]

then there exists \(C = C(b, N) > 0\) such that

\[EX^{2N} \leq C_r^{2N}.\]

**A. Cumulants.** In the following discussion we use the notation \(\langle \nu, f \rangle\) to denote the inner product of a function \(f\) and a measure \(\nu\) on \(\mathbb{Z}^d\), and we let \(R_n\) be the occupation measure of the nearest neighbor branching random walk with Poisson(1) offspring distribution. By the additivity and spatial homogeneity of the branching random walk, for any \(\psi \in C_c(\mathbb{Z}^d)\) and for each \(n \geq 1\) there exists a function \(\nu_n = \nu_n^\psi \in C_c(\mathbb{Z}^d)\) such that for any (nonrandom) initial configuration \(\mu\),

\[E^n \exp(\langle R_n, \psi \rangle) = \exp(\langle \mu, \nu_n^\psi \rangle).\]

Note that \(\nu_1 = \psi\). The assignment \(\psi \mapsto \nu_n^\psi\) is monotone in \(\psi\), but not in general linear. Setting \(\mu = \delta_x\) and conditioning on the first generation, we obtain

\[\exp(\nu_{n+1}(x)) = \sum_j Q_j \left( \frac{1}{2d + 1} \sum_e \exp(\psi(x + e) + \nu_n(x + e)) \right)^j\]

where \(\{Q_j\}\) is the offspring distribution (in the case of interest, the Poisson distribution with mean 1) and the inner sum is over the \(2d + 1\) nearest neighbors \(e\) of the origin in \(\mathbb{Z}^d\) (recall that the origin is
included in this collection, since particles of the branching random walk can stay at the same sites as their parents. Observe that if the offspring distribution is Poisson(1), then

\[
\nu_{n+1}(x) = \frac{1}{2d+1} \sum_{e} \exp(\psi(x + e) + \nu_n(x + e)) - 1.
\]

Define the cumulants \( \kappa_{h,n}(x) = \kappa_h^n(x) \) in the usual way:

\[
E^\mu \exp(\theta(R_n, \psi)) = \exp \left( \left\langle \mu, \sum_{h \geq 1} \theta^h \kappa_{h,n} \right\rangle \right), \quad \forall \theta \in \mathbb{R}.
\]

By the arguments of the preceding paragraph, \( \kappa_{1,1} = \psi \) and \( \kappa_{h,1} = 0 \) for all \( h \geq 2 \), and by (31),

\[
\sum_{h \geq 1} \theta^h \kappa_{h,n+1}(x) = \frac{1}{2d+1} \sum_{e} \exp \left\{ \sum_{h \geq 1} \theta^h \kappa_{h,n}(x + e) + \theta \psi(x + e) \right\} - 1.
\]

Consequently,

\[
\kappa_{h,n+1}(x) = \frac{1}{2d+1} \sum_{e} \sum_{m=1}^{h} \frac{1}{m!} \sum_{P_m(h)} \prod_{i=1}^{m} \{ \kappa_{h_i,n}(x + e) + \delta_1(h_i) \cdot \psi(x + e) \}
\]

where \( P_m(h) \) denotes the set of \( m \)-tuples \((h_1, h_2, \ldots, h_m)\) of positive integers whose sum is \( h \), and \( \delta_1(\cdot) \) is the Kronecker delta function. When \( h \geq 2 \), the \( m = 1 \) summand in (32) equals \( 1/(2d+1) \cdot \sum_e \kappa_{h,n}(x + e) = (P_1 \ast \kappa_{h,n})(x) \), hence,

\[
\kappa_{h,n+1}(x) = (P_1 \ast \kappa_{h,n})(x) + \Xi_{n+1}(x),
\]

where

\[
\Xi_{n+1}(x) = \Xi_{n+1}(x; h) := \frac{1}{2d+1} \sum_{e} \sum_{m=2}^{h} \frac{1}{m!} \sum_{P_m(h)} \prod_{i=1}^{m} \{ \kappa_{h_i,n}(x + e) + \delta_1(h_i) \psi(x + e) \}.
\]

Since \( \kappa_{h,1} = 0 \) for all \( h \geq 2 \), by iteration we then get

\[
\kappa_{h,n}(x) = \sum_{l=0}^{n-1} (P_l \ast \Xi_{n-l})(x).
\]

Consider now the special case \( \psi = \psi_{a,b} := \delta_a - \delta_b \) where \( a, b \in \mathbb{Z}^d \) and \( \delta_x \) is the Kronecker delta function. Fix \( 0 < \gamma < 2 - d/2 \) small, and let

\[
\eta = \eta(\gamma) = 2 - (d + \gamma)/2 > 0.
\]

Recall that in (22) in Lemma 4 we defined \( F_{n,h}(x; y; \beta) \) for \( \beta > 0 \), \( h \geq 1 \), \( n \in \mathbb{N} \) and \( x, y \in \mathbb{Z}^d \) as

\[
F_{n,h}(x; y; \beta) = F_{n,h;\gamma}(x, y; \beta) = \sum_{|\rho| < h} \sum_{l < n} \frac{1}{l^{\gamma/2}} \Phi_l(\beta(x + \rho), \beta(y + \rho)).
\]
Claim. For each \( h \geq 1 \) there exists \( C_h < \infty \) such that for all \( n \in \mathbb{N} \) and all \( x \in \mathbb{Z}^d \),

\[
|\kappa_{h,n}(x)| \leq C_h |a - b|^{h \gamma} n^{(h-1) - \gamma/2} \sum_{|\rho| < h} \sum_{l<n} \Phi_l(2^{-h} \beta(a - \rho), 2^{-h} \beta(b - \rho)).
\]

Moreover, for all \( h \geq 2 \), all \( n \in \mathbb{N} \) and all \( x \in \mathbb{Z}^d \),

\[
|\kappa_{h,n}(x)| \leq C_h |a - b|^{h \gamma} n^{(h-1) - \gamma/2} \sum_{|\rho| < h} \sum_{l<n} \Phi_l(2^{-h} \beta(a - \rho), 2^{-h} \beta(b - \rho)).
\]

In fact, when \( h = 1 \),

\[
|\kappa_{1,n}(x)| = |E^{\delta_y} (R_n, \psi)| = |G_n(a - x) - G_n(b - x)|
\leq C |a - b| \gamma \sum_{l<n} \frac{1}{F_{l/2}^2} \Phi_l(\beta(a - x), \beta(b - x))
\leq C |a - b| \gamma F_{n,1}(a - x, b - x; \beta),
\]

where in the middle inequality we used assertion (21) of Lemma 3. Furthermore, since \( \psi(x) \neq 0 \) if and only if \( x = a \) or \( b \), in which case \( |\psi(x)| = 1 \) and \( \inf_n C |a - b| \gamma F_{n,1}(a - x, b - x; \beta) > 0 \), we get that for all \( n \) and all \( x \),

\[
|\kappa_{1,n}(x) + \psi(x)| \leq C |a - b| \gamma F_{n,1}(a - x, b - x; \beta).
\]

Now suppose that the claim holds for \( 1, \ldots, h - 1 \), and we want to prove the claim for \( h \). First note that in the definition (33) of \( \Xi_n(x) \), only \( Y_{hi} \) for \( h_i < h \) are involved, hence by induction, (37) and relation (23) we get that for all \( n \) and \( x \),

\[
\Xi_n(x) \leq C |a - b|^{h \gamma} n^{(h-2)} \sum_{e m=2}^h \sum_{\mathcal{P}(m,h)} F_{n,h_1}(a - x + e, b - x + e; 2^{-(h_1-1)} \beta) : F_{n,h-h_1}(a - x + e, b - x + e; 2^{-(h-2)} \beta).
\]

The claims then follow from (34) and (24).

**B. Proof of (29) .** Suppose the initial configurations \( \mu^k \) satisfy the hypotheses of Theorem 1. For any \( a, b \in \mathbb{R}^d \), we want to estimate \( E^{\mu^k} |Y_k(t, a) - Y_k(t, b)|^m \). By Lemma 6 this can be done by setting \( \psi = 1 - \sqrt{k} a - \sqrt{k} b \) and estimating \( \langle \mu^k, \kappa_{h,k} \rangle \). By (36), for all \( h \geq 2 \),

\[
|\langle \mu^k, \kappa_{h,k} \rangle| \leq C_h |\sqrt{k} (a - b)|^{h \gamma} \gamma (kt)^{(h-1) - \gamma/2} \sum_{|\rho| < h} \sum_{l<k} \Phi_l(2^{-h} \beta(\sqrt{k} a + \rho - \cdot), 2^{-h} \beta((\sqrt{k} b + \rho - \cdot))).
\]

By assumption (41), we can find an \( A > 0 \) such that \( \text{supp}(\mu^k) \subseteq B(0, A \sqrt{k}) \) for all \( k \), where \( B(0, r) \) represents the ball of radius \( r \) around 0. We therefore have that for all \( k \) sufficiently large,

\[
\max_x \langle \mu^k, \sum_{l<k} \Phi_l(2^{-h} \beta(x - \cdot)) \rangle = \max_{|x| \leq A \sqrt{k}} \sum_{y l<k} \mu_k(y) \sum_{l<k} \Phi_l(2^{-h} \beta(x - y))
\leq C \sum_y \mu_k(y) \sum_{l<k} \Phi_l(x - y)
\leq C k^{2-d/2},
\]
where in the first inequality we used (19), and the last inequality is due to the relative compactness of \((\mu^k G_{kt})(\sqrt{t})/k^{2-d/2}\) assumed in (9). Hence when \(h \geq 2\),
\[
|\langle \mu^k, \kappa_{h,kt} \rangle| \leq Ck^{h\gamma/2+\eta(h-1)-\gamma/2}t^{(h-1)-\gamma/2} |a - b|^{h\gamma}.
\]
Plugging in \(\eta = 2 - (d + \gamma)/2\) gives us
\[
|\langle \mu^k, \kappa_{h,kt} \rangle| \leq Ck^{(2-d)/2}t^{(2-(d+\gamma))(h-1)-\gamma/2} |a - b|^{2h\gamma}.
\]
Noting that \(E^\mu_k (Y_k(t,a) - Y_k(t,b)) = 0\), by Lemma 6, we get
\[
E^\mu_k |Y_k(t,a) - Y_k(t,b)|^{2h} \leq Ct^{(2-(d+\gamma)/2)(h-1)-\gamma/2} |a - b|^{2h\gamma}.
\]
By choosing \(h\) large such that \(2h\gamma > d + 1\) we obtain (29).

C. Proof of (30). By the additivity and spatial homogeneity of the branching random walk, for any \(\psi \in C_c(\mathbb{Z}^d)\) and for all \(m, n \in \mathbb{N}\) there exists a function \(\nu_n = \nu_n^\psi \in C_c(\mathbb{Z}^d)\) such that for any (nonrandom) initial configuration \(\mu\),
\[
E^\mu \exp(\langle R_{n+m} - R_m, \psi \rangle) = \exp(\langle \mu, \nu_{(n,m)} \rangle).
\]
Letting \(\mu = \delta_x\) and conditioning on the first generation, we get
\[
\exp(\nu_{(n,m+1)}(x)) = E^\delta_x \exp(\langle R_{n+1+m} - R_{m+1}, \phi \rangle) = \sum_j Q_j \left( \frac{1}{2d + 1} \sum_e \exp(\nu_{(n,m)}(x + e)) \right)^j,
\]
where \(Q = \{Q_j\}_{j \geq 0}\) denotes the offspring distribution. In case where the offspring distribution is Poisson(1), the equation above implies
\[
(39) \quad \nu_{(n,m+1)}(x) = \frac{1}{2d + 1} \sum_e \exp(\nu_{(n,m)}(x + e)) - 1.
\]
Define the cumulants \(\kappa_{h,(n,m)}\) by
\[
E^\mu \exp(\theta \langle R_{n+m} - R_m, \psi \rangle) = \exp(\langle \mu, \sum_{h \geq 1} \theta^h \kappa_{h,(n,m)} \rangle), \quad \forall \theta \in \mathbb{R}.
\]
Then by (39),
\[
\sum_h \theta^h \kappa_{h,(n,m+1)}(x) = \frac{1}{2d + 1} \sum_e \exp \left[ \sum_h \theta^h \kappa_{h,(n,m)}(x + e) \right] - 1.
\]
Therefore
\[
(40) \quad \kappa_{h,(n,m+1)}(x) = \frac{1}{2d + 1} \sum_e \sum_{i=1}^h \frac{1}{i!} \sum_{P_1(h)} \prod_{j=1}^i \kappa_{h,(n,m)}(x + e),
\]
where \(P_1(h)\) denotes the set of \(i - \)tuples \((h_1, h_2, \ldots, h_i)\) of positive integers whose sum is \(h\). The \(m = 1\) summand in (40) equals \(1/(2d + 1) \cdot \sum_i \kappa_{h,(n,m)}(x + e) = (P_1 \ast \kappa_{h,(n,m)})(x)\), hence when \(h \geq 2\),
\[
\kappa_{h,(n,m+1)}(x) = (P_1 \ast \kappa_{h,(n,m)})(x) + \tilde{\Xi}_{n,m+1}(x),
\]
where
\[
\hat{\xi}_{n,m+1}(x) = \frac{1}{2d+1} \sum_{e} \sum_{i=2}^{h} \frac{1}{i!} \prod_{j=1}^{i} \kappa_{h,i,(n,m)}(x + e)
\]

By iteration we then get that for all \( h \geq 2, \)
\[
\kappa_{h,(n,m)}(x) = \sum \left( P_{i} \ast \hat{\xi}_{n,m-i}(x) \right).
\]

For \( \psi = 1_{a} \) for \( a \in \mathbb{Z}^{d}, \) by (17)
\[
\kappa_{1,(n,m)}(x) = E^{\hat{x}}(R_{m+n} - R_{m}, \psi) = \sum_{m \leq l < m+n} P_{l}(a - x) \leq C \sum_{m \leq l < m+n} \phi_{l}(\beta(a - x)).
\]

Furthermore, similarly as in proving the claim in Part A, using Lemma 5 and (42) we get that for all \( h,\) there exists \( C_{h} > 0 \) such that
\[
|\kappa_{h,(n,m)}(x)| \leq C_{h}n^{(2-d/2)(h-1)} \sum_{|\rho| < h} \sum_{m \leq l < m+n} \phi_{l}\left(2^{-(h-1)}\beta(a - x + \rho)\right).
\]

We are ready to verify (30). Setting \( \psi = 1_{\sqrt{\kappa_{a}}} \) and using (38), we get
\[
|\langle \mu^{k}, \kappa_{h,kt,k_{a}} \rangle| \leq Ck^{l(2-d/2)(h-1)}t^{l(2-d/2)(h-1)} \cdot k^{2-d/2}
\]
\[
= Ck^{h(2-d/2)} \cdot t^{l(2-d/2)(h-1)}.
\]

By Lemma 6 we then get
\[
E^{\mu^{k}} \left| Y_{k}(t + s, a) - Y_{k}(s, a) \right|^{2h} \leq C \cdot t^{(2-d/2)(2h-1)}.
\]

So by choosing \( h \) large such that \( (2 - d/2)(2h - 1) > 1 + d \) we obtain 30.

**Remark 7.** For general offspring distributions \( Q = \{Q_{j}\}, \) let \( f(x) = \log(\sum_{j} Q_{j}x^{j}) \) where \( x \geq 0. \)
If the offspring distribution \( Q \) has an exponentially decaying tail, then \( f(x) \) can be expanded around \( x = 1 \) as \( f(x) = \sum_{\ell=1}^{\infty} f^{(\ell)}(1)(x - 1)^{\ell} / \ell! \). Thus (31) turns into
\[
\nu_{n+1}(x) = \sum_{\ell=1}^{\infty} f^{(\ell)}(1) \left(\frac{1}{2d+1} \sum_{e} \exp \left( \psi(x + e) + \nu_{n}(x + e) \right) - 1 \right)^{\ell} / \ell!,
\]
and
\[
\sum_{h} \theta^{h}\kappa_{h,n+1}(x) = \sum_{\ell=1}^{\infty} f^{(\ell)}(1) \left(\frac{1}{2d+1} \sum_{e} \exp \left( \theta\psi(x + e) + \sum_{h} \theta^{h}\kappa_{h,n}(x + e) \right) - 1 \right)^{\ell} / \ell!.
\]

This enables us to express \( \kappa_{h,n+1}(x) \) in terms of \( \psi(x + e) \) and \( \kappa_{h,n}(x + e) \) similarly as in (32) and in (34) (note \( f^{(1)}(1) = 1 \) because \( Q \) has mean 1), and prove the Kolmogorov-Centsov criterion for the spatial variable. Similarly one can verify the Kolmogorov-Centsov criterion for the time variable.
2.3. Sufficient conditions for Assumption (9). Now we state some conditions that imply (9) and are easier to check.

**Proposition 1.** Let \( d = 2 \) or 3. Suppose that the initial configurations \( \mu^k \) are such that \( \mathcal{F}_k \mu^k \Rightarrow \mu \), and satisfy

\[
\lim_{t \to 0} \sup_k \max_x (\mu^k G_{kt})(x)/k^{2-d/2} = 0.
\]

Then (9) holds. In particular, if any of the following assumptions is satisfied, then (9) holds.

(i) In dimension 2, the maximal number of particles on a single site is bounded in \( k \), i.e., \( \sup_k \max_y \mu^k(y) < \infty \).

(ii) In dimension 3, there exist \( C_1, C_2 > 0 \) such that

\[
C_2 := \sup_k \max_x \sum_{y \in B(x, 3C_1 k^{1/6})} \mu^k(y) < \infty,
\]

where \( B(x, r) \) denotes the ball of radius \( r \) around \( x \) for any \( x \) and \( r \geq 0 \); that is, the number of particles in any ball of radius \( 3C_1 k^{1/6} \) is bounded in \( k \).

(iii) In dimension 2, \( \mu^k \) is such that \( \mu^k(y) \) is a decreasing function in \( |y| \), and there exists \( \alpha \in (0, 2) \) such that

\[
\mu^k(y) \leq C \left( \sqrt{k/(|y|^2 + 1)} \right)^\alpha, \quad \forall \ y, k.
\]

**Remark 8.** This proposition is a natural analogue of Proposition 1 in [Sugitani, 1989].

To prove Proposition [11] we will need the following result.

**Lemma 7.** For any function \( \psi \in C_c(\mathbb{R}^d) \) and each integer \( k \geq 1 \), define

\[
\Psi^k_t(x) = \sum_{y \in \mathbb{Z}^d} \psi(y/\sqrt{k}) G_{kt}(\sqrt{k}x - y)/k, \quad \text{for } x \in \mathbb{Z}^d/\sqrt{k} \text{ and } t \in \mathbb{Z}/k,
\]

and extend by linear interpolation elsewhere. Then

\[
\lim_{k \to \infty} \Psi^k_t(x) = \left[ (q_{\sigma^2 \psi} + \psi)/\sigma^2 \right](x),
\]

and the convergence is locally uniform in \( t \) and \( x \).

**Proof.** Pointwise convergence (46) follows from the local central limit theorem. To prove that the convergence is locally uniform, it suffices to show that the sequence of functions \( \{\Psi^k_t(x)\} \) is relatively compact in \( C(\mathbb{R}^{1+d}) \). For this, we use the Ascoli-Arzela criterion. First, we show that the functions \( \Psi^k_t(x) \) are uniformly bounded on any compact set in \( \mathbb{R}^{1+d} \). Denote by \( M \) the maximum of \( |\psi(x)| \). Then

\[
|\Psi^k_t(x)| \leq \sum_{y \in \mathbb{Z}^d} |\psi(y/\sqrt{k})| \cdot G_{kt}(\sqrt{k}x - y)/k
\]

\[
\leq M \sum_{y \in \mathbb{Z}^d} G_{kt}(\sqrt{k}x - y)/k
\]

\[
\leq Mt.
\]
Next, we show they are equi-continuous. Fix $\varepsilon > 0$, and set $\delta = \varepsilon/M$. By (47), $|\Psi_t^k| \leq \varepsilon$ for all $t \leq \delta$; thus,

$$|\Psi_t^k(x) - \Psi_t^k(y)| \leq 2\varepsilon, \quad \forall \ x, y \in \mathbb{R}^d \text{ and } s, t \leq \delta.$$ 

On the other hand, by (20), for all $t \geq \delta$ and $x \neq y \in \mathbb{R}^2$,

$$|\Psi_t^k(x) - \Psi_t^k(y)| \leq 2\varepsilon + \frac{\sqrt{k}|x - y|}{k} \sum_{k\delta \leq n \leq k} \frac{1}{\sqrt{n}} \sum_{z} |\psi(z/\sqrt{k})| \cdot \Phi_n(\beta(\sqrt{k}x - z), \beta(\sqrt{k}y - z))$$

$$\leq 2\varepsilon + \frac{\sqrt{k}|x - y|}{k} \sum_{k\delta \leq n \leq k} \frac{1}{\sqrt{n}^{d+1}} \cdot C\sqrt{k}^d$$

$$\leq 2\varepsilon + C\delta^{-(d-1)/2} \cdot |x - y|.$$ 

(In the second inequality we used the fact that $\sum_{z} |\psi(z/\sqrt{k})| \leq C\sqrt{k}^d$; this holds because $\psi$ is bounded and has compact support.) Finally, for all $x$ and all $\delta \leq s < t$,

$$|\Psi_t^k(x) - \Psi_s^k(x)| \leq M \sum_{k\delta \leq n \leq k} \sum_{z} P_n(\sqrt{k}x - z)/k$$

$$\leq M(t - s).$$

\[\square\]

**Proof of Proposition** 7 For any $\psi \in C_t(\mathbb{R}^d)$, by Lemma 7, $\Psi_t^k(x)$ converge to $[(q_{\sigma^2t} \ast \psi)/\sigma^2](x)$ in the local uniform topology. Therefore,

$$\sum_x (\mu^k G_{kt})(\sqrt{k}x)/k^2 \cdot \psi(x) = \frac{1}{k} \sum_y \mu^k(\sqrt{k}y) \cdot \Psi_t^k(y)$$

$$\rightarrow \langle \mu, [(q_{\sigma^2t} \ast \psi)/\sigma^2] \rangle \quad \text{('': $\mu^k(\sqrt{k})/k \Rightarrow \mu \in M_F(\mathbb{R}^d)$)}$$

$$= \langle [(q_{\sigma^2t} \ast \psi)/\sigma^2], \psi \rangle.$$ 

On the other hand, if we can show that $(\mu^k G_{kt})(\sqrt{k}x)/k^{2-d/2}$ is relatively compact in $C(\mathbb{R}^{1+d})$, then for any limit $F(t, x)$,

$$\sum_x (\mu^k G_{kt})(\sqrt{k}x)/k^2 \psi(x) = \sum_x (\mu^k G_{kt})(\sqrt{k}x)/k^{2-d/2} \cdot \psi(x) \cdot 1/\sqrt{k}^d \rightarrow \int_x F(t, x)\psi(x)dx.$$ 

Hence, $\langle [(q_{\sigma^2t} \ast \mu)/\sigma^2], \psi \rangle = \int_x F(t, x)\psi(x)dx$, which implies that (1) the measure $[(q_{\sigma^2t} \ast \mu)/\sigma^2]$ has density, and (2) $(\mu^k G_{kt})(\sqrt{k}x)/k^{2-d/2}$ converge to $[(q_{\sigma^2t} \ast \mu)/\sigma^2](x)$ in $C(\mathbb{R}^{1+d})$.

Now we show that (43) implies that $(\mu^k G_{kt})(\sqrt{k}x)/k^{2-d/2}$ is relatively compact in $C(\mathbb{R}^{1+d})$, by verifying the Ascoli-Arzela criterion. We first show that they are uniformly bounded on any compact set in $\mathbb{R}^{1+d}$. In fact, by (43), there exists $\delta > 0$ such that

$$\sup_k \max_x (\mu^k G_{k\delta})(\sqrt{k}x)/k^{2-d/2} \leq 1;$$
moreover, for all \( t \geq \delta \) and all \( x \),

\[
(\mu^k G_{kt})(\sqrt{kx})/k^{2-d/2} \\
\leq 1 + \sum_{k\delta \leq n \leq kt} \sum_z \mu^k(z) P_n(\sqrt{kx} - z)/k^{2-d/2} \\
\leq 1 + \sum_{k\delta \leq n \leq kt} C/n^{d/2} \cdot k/k^{2-d/2} \\
\leq C = C(t),
\]

where in the second inequality we used the facts that there exists \( C > 0 \) such that for all \( n \) and all \( x \in \mathbb{Z}^d \), \( P_n(x) \leq C/n^{d/2} \) (cf. Spitzer [1976], Proposition 6 on p72), and that the total number of particles \( \sum_z \mu^k(z) = O(k) \).

Next we show they are equi-continuous. In fact, for any \( \varepsilon > 0 \), by (43), there exists \( \delta > 0 \) such that

\[
\sup_{k} \max_{x} (\mu^k G_{k\delta})(\sqrt{kx})/k^{2-d/2} \leq \varepsilon;
\]

therefore, for all \( s, t \leq \delta \) and all \( x, y \),

\[
\sup_k |(\mu^k G_{ks})(\sqrt{kx})/k^{2-d/2} - (\mu^k G_{kt})(\sqrt{ky})/k^{2-d/2}| \leq 2\varepsilon;
\]

moreover, for all \( t \geq \delta \) and all \( x \neq y \), by (20),

\[
| (\mu^k G_{kt})(\sqrt{kx})/k^{2-d/2} - (\mu^k G_{kt})(\sqrt{ky})/k^{2-d/2} | \\
\leq 2\varepsilon + \frac{1}{k^{2-d/2}} \sum_{k\delta \leq n \leq kt} \sum_z \mu^k(z) |P_n(\sqrt{kx} - z) - P_n(\sqrt{ky} - z)| \\
\leq 2\varepsilon + C k^{1/2} |x - y| \sum_{k\delta \leq n \leq kt} \sum_z \mu^k(z) \frac{1}{\sqrt{n}} \Phi_n(\beta(\sqrt{kx} - z), \beta(\sqrt{ky} - z)) \\
\leq 2\varepsilon + C k^{1/2} |x - y| \sum_{k\delta \leq n \leq kt} \frac{1}{\sqrt{n}} \delta^{d/2} \cdot k \\
\leq 2\varepsilon + C \delta^{-(d-1)/2} |x - y|;
\]

and for all \( x \) and all \( \delta \leq s < t \),

\[
| (\mu^k G_{kt})(\sqrt{kx})/k^{2-d/2} - (\mu^k G_{ks})(\sqrt{kx})/k^{2-d/2} | \\
= \frac{1}{k^{2-d/2}} \sum_{k\delta \leq n \leq kt} \sum_z \mu^k(z) P_n(\sqrt{kx} - z) \\
\leq \frac{C}{k^{2-d/2}} \sum_{k\delta \leq n \leq kt} k/n^{d/2} \\
\leq \begin{cases} 
C \log(t/s) \leq C(t-s)/\delta, & \text{if } d = 2; \\
C(1/\sqrt{s} - 1/\sqrt{t}) \leq C(t-s)/\delta^{3/2}, & \text{if } d = 3.
\end{cases}
\]
We have therefore proved that (43) implies the relative compactness of \((\mu^k G_{kt})(\sqrt{k}x)/k^{2-d/2}\). Next we show that any of the conditions in (i)~(iii) implies (43).

(i) For all \(x \in \mathbb{R}^2\) and all \(t \geq 0\),

\[
(\mu^k G_{kt})(x)/k = \frac{1}{k} \sum_{n \leq kt} \sum_{z} \mu^k(z) P_n(x - z) \\
\leq \frac{C}{k} \sum_{n \leq kt} 1 = Ct,
\]

therefore (43) holds.

(ii) In order to verify (43), by (17), it suffices to show that

\[
\lim_{t \to 0} \sup \max_x \sum_{n \leq kt} \sum_{y} \mu^k(y) \phi_n(\beta(x - y))/\sqrt{k} = 0.
\]

Claim. There exists \(C_3 > 0\) such that for all \(k, n\) and all pairs \(x, y \in \mathbb{Z}^d\) with \(|x - y| \geq C_1 k^{1/6}\),

\[
\sqrt{k} \phi_n(\beta(x - y)) \leq C_3 \sum_{z \in B(y, C_1 k^{1/6})} \phi_n(\beta(x - z)).
\]

In fact, the above inequality is equivalent to

\[
\sqrt{k} \leq C_3 \sum_{|y - x| \leq C_1 k^{1/6}} \exp \left( \frac{\beta^2(|x - y|^2 - |x - z|^2)}{n} \right), \forall |x - y| \geq C_1 k^{1/6}.
\]

But this holds trivially since when \(x \notin B(y, C_1 k^{1/6})\), there is a positive proportion of integer points \(z\) in the ball \(B(y, C_1 k^{1/6})\) such that \(|x - y| \geq |x - z|\), and the proportion does not depend on \(k, x, y\). Now let us estimate \(\sum_{n \leq kt} \sum_{y} \mu^k(y) \phi_n(\beta(x - y))/\sqrt{k}\): For any fixed \(k\) and \(x\), this sum can be written as the sum of the following two terms:

\[
I := \sum_{n \leq kt} \sum_{|y - x| \leq C_1 k^{1/6}} \mu^k(y) \phi_n(\beta(x - y))/\sqrt{k},
\]

and

\[
II := \sum_{n \leq kt} \sum_{|y - x| > C_1 k^{1/6}} \mu^k(y) \phi_n(\beta(x - y))/\sqrt{k}.
\]

As to term \(I\), we have

\[
I \leq \sum_{n \leq kt} \sum_{|y - x| \leq C_1 k^{1/6}} \mu^k(y) \cdot C/n^{3/2}/\sqrt{k} \\
\leq \sum_{n \leq kt} C_2 \cdot C/n^{3/2}/\sqrt{k} \\
\leq C/\sqrt{k},
\]
where in the second inequality we used (44). And by the claim and (44),
\[
II \leq \sum_{n \leq kt} \sum_{|y-x| > C_1 k^{1/6}} \mu^k(y)/\sqrt{k} \cdot C_3 \sum_{z \in B(y,C_1 k^{1/6})} \phi_n(\beta(x-z))/\sqrt{k}
\leq C \sum_{n \leq kt} \sum_{z} \phi_n(\beta(x-z)) \cdot \sum_{y \in B(z,C_1 k^{1/6})} \mu^k(y)/k
\leq \sum_{n \leq kt} C/k
\leq Ct.
\]
Therefore (48) holds.

(iii) In order to verify (43), by (17), it suffices to show that
\[
(49) \quad \lim_{t \to 0} \sup_{k} \max_{x} \sum_{n \leq kt} \sum_{y} \mu^k(y) \phi_n(\beta(x-y))/k = 0.
\]
By assumption, \( \mu^k(y) \) is a decreasing function of \(|y|\); so is \( \phi_n(\beta y) \). Therefore, by Lemma 8 below, the last term is bounded by \( \sum_{n \leq kt} \sum_{y} \mu^k(y) \phi_n(\beta y)/k \), which, by assumption (45), can be further bounded by
\[
C \sum_{n \leq kt} \frac{1}{n \cdot k} \sum_{y} \left( \sqrt{\frac{k}{|y|^2 + 1}} \right)^{\alpha} e^{-\beta^2 |y|^2 / 2n/k}
\leq C \sum_{n \leq kt} \frac{1}{n \cdot k} \int_{x \in \mathbb{R}^2} |x|^{-\alpha} e^{-\beta^2 |x|^2 / 2n/k} dx
\leq C \sum_{n \leq kt} \frac{1}{n} (n/k)^{-\alpha + 1} \int_{x \in \mathbb{R}^2} |x|^{-\alpha} e^{-\beta^2 |x|^2 2/k} dx
\leq C \frac{1}{k} \sum_{n \leq kt} \left( \frac{n}{k} \right)^{-\alpha/2}
\leq C \int_{0}^{t} s^{-\alpha/2} ds
= O(t),
\]
where the third inequality and the last equation hold because \( \alpha < 2 \) by assumption.

Remark 9. In dimension 2, if the assumption in (iii) is satisfied, then the radius of the support of \( \mu^k \) will be of order \( \sqrt{k} \). This is because we need \( \sum_{y} \mu^k(y) = O(k) \), hence for some \( C > 0 \),
\[
\sum_{y \in \text{Supp}(\mu^k)} \left( \sqrt{k/(|y|^2 + 1)} \right)^{\alpha} \geq Ck,
\]
i.e.,
\[
\sum_{y \in \text{Supp}(\mu^k)} \left( 1/\sqrt{|y|^2 + 1} \right)^{\alpha} \geq Ck^{1-\alpha/2}.
\]
But for any $r$,
\[
\sum_{|y| \leq r} \left( \frac{1}{\sqrt{|y|^2 + 1}} \right)^\alpha = O \left( \int_{|y| \leq r} \left( \frac{1}{\sqrt{|y|^2 + 1}} \right)^\alpha dy \right)
\]
\[
= O \left( \int_{0}^{r} \left( \frac{1}{\sqrt{s^2 + 1}} \right)^\alpha \cdot s \, ds \right)
\]
\[
= O(r^{2-\alpha}),
\]
so in order that $O(r^{2-\alpha}) \geq C k^{1-\alpha/2}$, we need $r = O(k^{1/2})$.

**Remark 10.** In dimension 3, if $\mu^k$ is such that $\mu^k(y)$ is a decreasing function in $|y|$, and there exists $\alpha \in (0, 2)$ such that
\[
\mu^k(y) \leq C \left( \frac{\sqrt{k}/(|y|^2 + 1)}{\sqrt{k}} \right)^\alpha, \quad \forall \, y, k,
\]
then using the similar proof as in (iii) we can show that (45) holds. But in fact, (50) cannot be satisfied. The reason is that in order $\mu^k(y) \geq 1$, we must have that for some $C > 0$,
\[
1 \leq C \left( \frac{\sqrt{k}/(|y|^2 + 1)}{\sqrt{k}} \right)^\alpha \]
which implies that
\[
|y| \leq C k^{1/2 - 1/(2\alpha)} = o(k^{1/4}).
\]
On the other hand, we need $\sum_y \mu^k(y) = O(k)$, therefore for some $C > 0$,
\[
\sum_{|y| = o(k^{1/4})} \left( \frac{\sqrt{k}/(|y|^2 + 1)}{\sqrt{k}} \right)^\alpha \geq C k,
\]
or
\[
\sum_{|y| = o(k^{1/4})} \left( \frac{1}{\sqrt{|y|^2 + 1}} \right)^\alpha \geq C k^{(3-\alpha)/2}.
\]
However,
\[
\sum_{|y| = o(k^{1/4})} \left( \frac{1}{\sqrt{|y|^2 + 1}} \right)^\alpha = O \left( \int_{|y| = o(k^{1/4})} \left( \frac{1}{\sqrt{|y|^2 + 1}} \right)^\alpha \, dy \right)
\]
\[
= O \left( \int_{0}^{o(k^{1/4})} \left( \frac{1}{\sqrt{r^2 + 1}} \right)^\alpha \cdot r^2 \, dr \right)
\]
\[
= o(k^{(3-\alpha)/4}) = o(k^{(3-\alpha)/2}),
\]
contradiction with (51).

**Lemma 8.** Suppose that $f$ and $g$ are two nonnegative functions on $\mathbb{Z}^d$, and $f$ has compact support. Suppose further that both $f(x)$ and $g(x)$ are decreasing functions in $|x|$, then
\[
\sum_y f(y)g(x-y) \leq \sum_y f(y)g(y), \quad \forall \, x.
\]
Proof. Since \( f(x) \) is a decreasing function in \(|x|\) and has compact support, we can enumerate its positive values, say \( a_1 \geq \ldots \geq a_n > 0 \). We can also enumerate the values of \( g \), say \( b_1 \geq \ldots b_n \geq \ldots \). To show (52), it then suffices to show that
\[
\sup_{i_1, \ldots, i_n} \sum_{k=1}^n a_k b_{i_k} = \sum_{k=1}^n a_k b_k.
\]
But this is easily seen to be true. \( \square \)

3. Proof of Theorem 2: Spatial epidemics in dimensions \( d = 2, 3 \)

3.1. Strategy. The strategy is the same as that used by Lalley (2007) in the 1–dimensional case: Since the law of the SIR-d epidemic with village size \( N \) is absolutely continuous relative to that of its branching envelope, and since the branching envelopes converge weakly, after renormalization, to super-Brownian motion, it suffices to prove that the likelihood ratios converge weakly to the likelihood ratio (12) of the appropriate Dawson-Watanabe process relative to super-Brownian motion. The one- and higher-dimensional cases differ only in the behavior of the occupation statistics that enter into the likelihood ratios.

3.2. Modified SIR-d epidemic. As in the one-dimensional case, it is technically easier to work with the likelihood ratio for a modification of the SIR-d epidemic. Recall that (a) when an infected individual attempts to infect a recovered individual in an SIR epidemic, the attempt fails; and (b) when two (or more) infected individuals simultaneously attempt to infect the same susceptible individual, all but one of the attempts fail. Call an occurrence of type (a) an errant attempt, and an occurrence of type (b) a collision. In the modified SIR epidemic, collisions are not allowed, and there can be at most one errant attempt at any site/time. A formal specification of the modified SIR epidemic uses a variation of the standard coupling described in section 1.2, as follows:

Modified Standard Coupling: Particles are colored red or blue; red particles represent infected individuals in the modified SIR epidemic. Each particle produces a random number of offspring, according to the Poisson(1) distribution, which then randomly move to neighboring sites. Once situated, these offspring are assigned colors according to the following rules:

(A) Offspring of blue particles are blue; offspring of red particles may be either red or blue.
(B) At any site/time \((x, t)\) there is at most one blue offspring of a red parent.
(C) Given that at site \(x\) and time \(t\) there are \(y\) offspring of red parents, the conditional probability \( \kappa_N(y) = \kappa_{N,t,x}(y) \) that one of them is blue is
\[
\kappa_N(y) = \{yR/N\} \land 1, \quad \text{where}
\]
\[
R = R^N_t(x) = \sum_{s<t} Y^N_s(x)
\]
and \(Y^N_t(x)\) is the number of red particles at site \(x\) in generation \(t\). (Thus, \(R = R^N_t(x)\) is the number of recovered individuals at site \(x\) at time \(t\).) The red particle process is the modified SIR epidemic.

Proposition 2. For each \(N \geq 1\), versions of the SIR epidemic and the modified SIR epidemic can be constructed on a common probability space in such a way that (i) the initial configurations \(\mu^N\) of infected individuals are identical, and satisfy the hypothesis (14) of Theorem 2; and (ii) the
discrepancy \( D_t(x) \) between the two processes at site \( x \) and time \( t \) (that is, the absolute difference in number of infected individuals) satisfies
\[
\max_{t,x} D_t(x) = o_P(N^\alpha).
\]

This implies that after Feller-rescaling, the SIR-\( d \) epidemic and the modified SIR-\( d \) epidemic are indistinguishable. Consequently, to prove Theorem 2 it suffices to prove the corresponding result for the modified epidemic.

**Proof of Proposition 2.** This is essentially the same as the proof of Proposition 3 in Lalley (2007), except that different estimates for the numbers of collisions and errant infection attempts in the SIR-\( d \) epidemic are necessary. These are given in Lemma 9 below. \( \square \)

**Lemma 9.** For each pair \((n,x) \in \mathbb{N} \times \mathbb{Z}^d\), let \( \Gamma_n^N(x) \) and \( A_n^N(x) \) be the number of collisions and the number of errant infection attempts, respectively, at site \( x \) and time \( n \) in the SIR-\( d \) epidemic with village size \( N \). Assume that the hypotheses (44)-(45) of Theorem 2 are satisfied, for some \( \alpha \leq 1/(3 - d/2) \). Then
\[
\sum_n \sum_x \{ \Gamma_n^N(x) + (A_n^N(x) - 1)_+ \} = o_P(N^\alpha).
\]

The proof of this lemma makes use of the following result.

**Lemma 10.** [Proposition 28 in Lalley and Zheng (2007)] Denote by \( U_n(x) \) the number of particles at \( x \) at time \( n \) of a BRW started by one particle at the origin, then
\[
EU_n(x)^2 = P_n(x) + \sigma^2 \sum_{i=0}^{n-1} \sum_z P_i(z) P_{n-i}^2(x - z),
\]
where \( \sigma^2 \) is the variance of the offspring distribution.

**Proof of Lemma 2** Since the life length of the process is \( O_p(N^\alpha) \), it suffices to show that for any \( t > 0 \),
\[
\sum_{n \leq N^{\alpha t}} \sum_x \{ \Gamma_n^N(x) + (A_n^N(x) - 1)_+ \} = o_P(N^\alpha).
\]

Consider first the number \( \Gamma_n^N(x) \) of collisions at site \( x \) and time \( n \). For any susceptible individual \( \eta \), a collision occurs at \( \eta \) if and only if there is some pair \( \xi, \zeta \) of infected individuals at neighboring sites that simultaneously attempt to infect \( \eta \). Therefore given the evolution up to time \( n \), the conditional expectation of \( \Gamma_{n+1}^N(x) \) is bounded by \( C(\sum e X_n^N(x + e))^2/N \). We want to show that
\[
\sum_{n \leq N^{\alpha t}} \sum_x (X_n^N(x))^2/N = o_p(N^\alpha).
\]

By the dominance of BRW over SIR epidemic, if we denote by \( U_n(x) \) the number of particles at \( x \) at time \( n \) of a BRW started by one particle at the origin, and \( x_i, i = 1, 2, \ldots \), the position of the initial particles of our epidemic model, then
\[
E(X_n^N(x))^2 \leq \sum_i EU_n(x - x_i)^2 + 2 \sum_{i \neq j} P_n(x - x_i)P_n(x - x_j),
\]
which, in dimension 3, by Lemma 10 can be bounded by \( C \sum_i P_n(x - x_i) + 2 \sum_{i \neq j} P_n(x - x_i)P_n(x - x_j) \). Therefore
\[
\sum_{n \leq N^{\alpha t}} \sum_x E(X_n^N(x))^2 \leq C \sum_{n \leq N^{\alpha t}} (CN^\alpha + CN^{2\alpha}/\sqrt{n})
\]
(59)
\[
= O(N^{2\alpha}),
\]
which is \( o(N \times N^\alpha) \) since \( \alpha \leq 2/3 \). In dimension 2, again by Lemma 10, \( EU_n(x)^2 \leq C(1 + \log n)P_n(x) \), therefore
\[
\sum_{n \leq N^{\alpha t}} \sum_x E(X_n^N(x))^2 \leq C \sum_{n \leq N^{\alpha t}} (C(1 + \log n)N^\alpha + CN^{2\alpha}/n)
\]
(60)
\[
= O(N^{2\alpha} \log N),
\]
which is also \( o(N \times N^\alpha) \) since \( \alpha \leq 1/2 \).

Now consider the number \( A_n^N(x) \) of errant infection attempts at site \( x \) and time \( n \). In order that there be more than one errant attempt, either (i) two or more infected individuals must simultaneously try to infect a recovered individual, or (ii) infected individuals must attempt to infect more than one recovered individual. The number of occurrences of type (i) during the course of the epidemic is \( o_P(N^\alpha) \), by the same argument that proved (58). Thus, it suffices to bound the number of errant attempts of type (ii). This is bounded by the number \( B_n^N(x) \) of pairs \( \varrho, \varrho' \) of recovered individuals at site \( x \) and time \( n \) that are subject to simultaneous infection attempts. Clearly,
\[
B_n^N(x) \leq \sum_{\xi, \theta} \sum_{\zeta, \varrho'} Z_{\xi, \varrho} Z_{\zeta, \varrho'}
\]
where the sums are over all pairs \( ((\xi, \varrho), (\zeta, \varrho')) \) in which \( \varrho, \varrho' \) are recovered individuals at site \( x \) and time \( n \) and \( \xi, \zeta \) are infected individuals at neighboring sites, and \( Z_{\xi, \varrho} \) and \( Z_{\zeta, \varrho'} \) are independent Bernoulli\((1/(2d + 1)N)) \). Hence,
\[
E(B_{n+1}^N(x) \mid G_n) \leq C \left( \sum_{\epsilon} X_n^N(x + \epsilon) \right)^2 (R_n^N(x)/N)^2.
\]
By Theorem 1 and the dominance of BRW over SIR epidemic, for all \( \epsilon > 0 \), there exists \( C > 0 \) such that with probability \( \geq 1 - \epsilon \),
\[
\max_x R_{N^{\alpha t}}^N(x) \leq CN^{\alpha(2-d/2)}.
\]
Note further that
\[
\sum_{n \leq N^{\alpha t}} \sum_x E \left( \sum_{\epsilon} X_n^N(x + \epsilon) \right)^2 \leq C \sum_{n \leq N^{\alpha t}} \sum_x E(X_n^N(x))^2,
\]
which, by (60) and (59), is bounded by \( CN^{2\alpha} \log N \) in dimension 2 and \( CN^{2\alpha} \) in dimension 3. Therefore, by enlarging \( C \) if necessary we have that with probability \( \geq 1 - 2\epsilon \), the following holds:
\[
\sum_{n \leq N^{\alpha t}} \sum_x \left( \sum_{\epsilon} X_n^N(x + \epsilon) \right)^2 \left( R_n^N(x)/N \right)^2 \leq CN^{2\alpha(2-d/2)} N^{2\alpha} \log N/N^2 = o(N^\alpha).
\]
\( \Box \)
3.3. Convergence of likelihood ratios. In view of Proposition 2 to prove Theorem 2 it suffices to prove the corresponding result for the modified SIR epidemic defined in §3.2. For this, we shall analyze likelihood ratios. Denote by $Q_N$ the law of the modified SIR epidemic, and by $P_N$ the law of the branching envelope. Recall (cf. the modified standard coupling) that in the modified SIR process there can be at most one errant infection attempt, and no collisions, at any site/time $x, t$. Given the evolution of the process up to time $t - 1$, infection attempts at site $x$ and time $t$ are made according to the same law as are offspring in the branching envelope; the conditional probability that one of the attempts is errant is $\kappa_N(y)$ (see equation (53)). Consequently, the likelihood ratio $dQ_N/dP_N$ at the sample evolution $X_t := \{X_t^N(x)\}_{x,t}$ is

$$
\frac{dQ_N}{dP_N} = \prod_{t \geq 1} \prod_{x \in \mathbb{Z}^d} \frac{p(y|\lambda)(1 - \kappa_N(y)) + p(y + 1|\lambda)\kappa_N(y + 1)}{p(y|\lambda)},
$$

where

$$
y = X_t^N(x),$$

$$\lambda = \lambda_t^N(x) = \sum_e X_{t-1}^N(x + e)/(2d + 1), \text{ and}$$

$$p(k|\lambda) = \lambda^k e^{-\lambda}/k!.$$ 

By the same calculation as in Lalley (2007), equation (53), this can be rewritten as

$$
\frac{dQ_N}{dP_N} = (1 + \varepsilon_N) \exp \left\{ -\sum_t \sum_x \Delta_t^N(x) \theta_t^N(x) - \frac{1}{2} \sum_t \sum_x \Delta_t^N(x)^2 \theta_t^N(x)^2 \right\},
$$

where

$$
\Delta_t^N(x) := (X_t^N(x) - \lambda_t^N(x))/N^\alpha,$$

$$\theta_t^N(x) := R_t^N(x)/N^{1-\alpha}; \text{ and}$$

$$\varepsilon_N = o_p(1) \text{ under } P_N.$$ 

That the error term $\varepsilon_N$ is $o_p(1)$ follows by an argument nearly identical to the proof of Lemma 9.

Observe that under $P_N$, the increments (in $t$) of the first sum in the exponential constitute a martingale difference sequence. Furthermore, the quantities $\Delta_t^N(x)$ in equation (62) are the atoms of the orthogonal martingale measures $M_N$ associated with the branching random walks $X_N$. See Lalley (2007) for the analogous representation in the one-dimensional case, and Walsh (1986) for background on stochastic integration against orthogonal martingale measures. The martingale measures $M_N$ can be defined by their actions on test functions $\psi \in C_c^\infty(\mathbb{R}^d)$. Write $\langle \mu, \psi \rangle$ for the integral of $\psi$ against a finite Borel measure $\mu$ on $\mathbb{R}^d$, and $\mathcal{F}_k$ for the Feller-Watanabe rescaling operator $4$; then

$$
M_t^N(\psi) = \langle \mathcal{F}_{N^\alpha} X_N^N, \psi \rangle - \langle \mathcal{F}_{N^\alpha} X_0^N, \psi \rangle - \int_0^t \langle \mathcal{F}_{N^\alpha} X_{N^\alpha s}^N, A_{N^\alpha} \psi \rangle \, ds
$$

where $A_k$ is the difference operator

$$
A_k \psi(x) = \left( \sum_e \psi(x + e/\sqrt{k}) - (2d + 1)\psi(x) \right) / [(2d + 1)k^{-1}] .
$$
The first sum in the exponential of equation (62) can be expressed as a stochastic integral against the orthogonal martingale measure $M^N$:

\[
\sum_{t \geq 1} \sum_{x \in \mathbb{Z}^d} \Delta^N_t(x) \varphi^N_t(x) = \int \int \theta^N(t, x) M^N (dt, dx),
\]

where

\[
\theta^N(t, x) = \rho^{N}_{\alpha} N^\alpha(t, \sqrt{N^\alpha x})/N^{1-\alpha}.
\]

**Proposition 3.** Let $X$ be the Dawson-Watanabe process with initial configuration $\mu$ and variance parameter $\sigma^2$, and let $M(dt, dx)$ and $L_t(x)$ be the associated orthogonal martingale measure and local time density process. Then under $P^N$, given the hypotheses of Theorem 2, as $N \to \infty$,

\[
(F^{\alpha} X^N, \theta^N, M^N) \Rightarrow (X, 0, M) \quad \text{if} \quad \alpha < 1/(3 - d/2) \quad \text{and}
\]

\[
(F^{\alpha} X^N, \theta^N, M^N) \Rightarrow (X, L, M) \quad \text{if} \quad \alpha = 1/(3 - d/2).
\]

**Proof.** Given the weak convergence of the second margin $\theta^N$, the joint convergence of the triple follows by the same argument as in Proposition 4 of Lalley (2007). The asymptotic behavior of the processes $\theta^N$ follows from Theorem 1. □

**Corollary 1.** If $\alpha < 1/(3 - d/2)$ then under $P^N$, as $N \to \infty$,

\[
\frac{dQ^N}{dP^N} \longrightarrow 1 \quad \text{in probability}
\]

provided that the hypotheses of Theorem 2 on the initial configurations are satisfied.

**Proof.** Proposition 3 implies that the sums (63) converge to zero in probability as $N \to \infty$. That the second sum in the likelihood ratio (62) also converges to zero in probability follows by the same argument as in the one-dimensional case (see the proof of equation (60) in Lalley (2007)). □

**Proof of Theorem 2.** Corollary 1 implies that the modified SIR epidemics have the same scaling limit as their branching envelopes when $\alpha < 1/(3 - d/2)$. Thus, to complete the proof of Theorem 2, it suffices to prove the assertion (66) when $\alpha = 1/(3 - d/2)$. For this, it suffices to show that the two sums in the exponential of equation (62) converge to the corresponding integrals in the exponential of equation (12). The convergence of the first sum follows from Proposition 3 and the representation (63). By the same argument as in the proof of Corollary 4 of Lalley (2007),

\[
\sum_{n} \sum_{x} \Delta^N_n(x) \varphi^N_n(x) = \int \int \theta^N(t, x) M^N (dt, dx) \Rightarrow \int \int L_t(x) M(dt, dx).
\]

The convergence of the second sum

\[
A^N := \sum_{n} \sum_{x} \Delta^N_n(x)^2 \varphi^N_n(x)^2 \Rightarrow \langle X_t, (L_t)^2 \rangle dt
\]

follows by an argument similar to the proof of equation (60) in Lalley (2007). The idea is that if one substitutes the conditional expectation $\lambda^N_n(x)/N^{2\alpha} = E(\Delta^N_n(x)^2 | G_{n-1})$ for the quantity $\Delta^N_n(x)^2$
in the sum \( (65) \), then the modified sum converges; in particular, by Theorem 1 and Watanabe’s theorem,

\[
B^N := \sum_n \sum_x \lambda_n^N(x)/N^{2\alpha} \times [R_n^N(x)/N^{1-\alpha}]^2
\]

\[
= \frac{1}{N^\alpha} \sum_n \sum_x \left( \sum_{e} X_n^N(x + e)/(2d + 1) \right)/N^\alpha \times [R_n^N(x)/N^{\alpha(2-d/2)}]^2
\]

\[
\Rightarrow \int (X_t, (L_t)^2) \, dt,
\]

where the second equation holds because \( \alpha = 1/(3 - d/2) \). Therefore, it suffices to show that replacing \( \Delta_n^N(x)^2 \) by its conditional expectation has an asymptotically negligible effect on the sum, that is,

\[
A^N - B^N = o_p(1).
\]

By a simple variance calculation (see Lalley (2007) for the one-dimensional case), this reduces to proving that

\[
(67) \quad \sum_n \sum_x (\lambda_n^N(x))^2/N^{4\alpha} \times [R_n^N(x)/N^{\alpha(2-d/2)}]^4 = o_p(1).
\]

In fact, for all \( \epsilon > 0 \), there exists \( C > 0 \) such that with probability \( \geq 1 - \epsilon \),

\[
\max_x R_n^N(x) \leq CN^{\alpha(2-d/2)}.
\]

Note further that

\[
\sum_{n \leq N^\alpha t} \sum_x E(\sum_{e} X_n^N(x + e))^2 \leq C \sum_{n \leq N^\alpha t} \sum_x E(X_n^N(x))^2,
\]

which, by \((60)\) and \((59)\), is bounded by \( CN^{2\alpha} \log N \) in dimension 2 and \( CN^{2\alpha} \) in dimension 3. Therefore, by enlarging \( C \) if necessary we have that with probability \( \geq 1 - 2\epsilon \), the following holds:

\[
\sum_{n \leq N^\alpha t} \sum_x (\lambda_n^N(x))^2/N^{4\alpha} \times [P_n^N(x)/N^{\alpha(2-d/2)}]^4 \leq CN^{2\alpha} \log N/N^{4\alpha} = o(1).
\]

\[\square\]

4. Appendix: Proofs of Lemmas 2-5

4.1. Proofs of Lemmas 2-3. The strategy is to consider the regions \( |x| \leq (2Ln \log n)^{1/2} \) and \( |x| \geq (Ln \log n)^{1/2} \) separately. We begin with the unbounded region. By Hoeffding’s inequality, since the increments of \( S_n \) are no larger than 1 in modulus,

\[
P_n(x) \leq P(|S_n| \geq |x|) \leq 2d \exp(-|x|^2/(2dn)).
\]

Now for \( 0 < \beta < 1/\sqrt{d} \) and \( L = L(\beta) \) sufficiently large,

\[
\exp(-|x|^2/(2dn)) \leq \exp(-\beta^2|x|^2/(2n))/n^{(d+1)/2}, \quad \forall |x| \geq \sqrt{Ln \log n}.
\]

Thus,

\[
(68) \quad P_n(x) \leq C \exp(-\beta^2|x|^2/(2n))/n^{(d+1)/2} = C\phi_n(\beta x)/\sqrt{n}, \quad \forall |x| \geq \sqrt{Ln \log n},
\]
and

\begin{equation}
|P_n(x) - P_n(y)| \leq C \Phi_n(\beta x, \beta y) / \sqrt{n} \\
\leq C \left( \frac{|x - y|}{\sqrt{n}} \land 1 \right) \Phi_n(\beta x, \beta y), \quad \forall |x|, |y| \geq \sqrt{Ln \log n}.
\end{equation}

This proves inequalities (17) and (20) for \( x \) and \( y \) outside the ball of radius \( (Ln \log n)^{1/2} \).

To deal with the region \( |x| \leq (2Ln \log n)^{1/2} \) we shall use the following crude estimate, valid for all points \( x \in \mathbb{Z}^d \) (Theorem 2.3.5 in Lawler and Limic (2007)):

\begin{equation}
|P_n(x) - \sigma^{-d} \phi_n(x/\sigma)| \leq C/(\sqrt{n} \cdot n).
\end{equation}

For \( \beta = \beta(L) > 0 \) sufficiently small,

\begin{equation}
\phi_n(\beta x) \geq 1/(\sqrt{n} \cdot n^{d/2}), \quad \forall |x| \leq \sqrt{2Ln \log n};
\end{equation}

consequently,

\begin{equation}
|P_n(x) - \sigma^{-d} \phi_n(x/\sigma)| \leq C \phi_n(\beta x)/\sqrt{n}, \quad \forall |x| \leq \sqrt{2Ln \log n}.
\end{equation}

This obviously implies (17) for \( x \) in the region \( |x| \leq (2Ln \log n)^{1/2} \), and hence, together with the argument of the preceding paragraph, completes the proof of (17).

Similar arguments can be used to establish inequality (20) for points \( x \) and \( y \) in the ball of radius \( (Ln \log n)^{1/2} \) centered at the origin. First, it is easily seen that for sufficiently small \( \beta > 0 \),

\begin{equation}
|\phi_n(x) - \phi_n(y)| \leq C ((|x - y|/\sqrt{n}) \land 1) \Phi_n(\beta x, \beta y), \quad \forall x, y \in \mathbb{R}^d
\end{equation}

Hence, by (70), (20) holds for for \( x \) and \( y \) in the ball of radius \( (Ln \log n)^{1/2} \). Therefore, since the choice of \( L \) is arbitrary, to complete the proof of (20) it suffices to consider the case where \( |x| \leq (Ln \log n)^{1/2} \) and \( |y| \geq (2Ln \log n)^{1/2} \). In this case, choose a point \( z \) in the annulus \( |z| \in ((Ln \log n)^{1/2}, (2Ln \log n)^{1/2}) \) such that \( |x - z| + |z - y| \leq 2|x - y| \). Using the fact that (20) holds for each of the pairs \( x, z \) and \( y, z \), we have

\begin{equation}
|P_n(x) - P_n(z)| \leq C ((|x - z|/\sqrt{n}) \land 1) \Phi_n(\beta x, \beta z) \leq 2C ((|x - z|/\sqrt{n}) \land 1) \Phi_n(\beta x, \beta y)
\end{equation}

and

\begin{equation}
|P_n(z) - P_n(y)| \leq C (|z - y|/\sqrt{n} \land 1) \Phi_n(\beta z, \beta y) \leq C (|z - y|/\sqrt{n} \land 1) \Phi_n(\beta y, \beta y).
\end{equation}

Consequently,

\begin{equation}
|P_n(x) - P_n(y)| \leq C ((|x - y|/\sqrt{n}) \land 1) \Phi_n(\beta x, \beta y).
\end{equation}

This completes the proof of (20).

**Proof of (19)** when \( d = 3 \). The following argument works for all \( d \geq 3 \). Firstly, \( \sum_{kT \leq n \leq kT} \phi_n(\beta x) \) is bounded by \( \sum_{kT \leq n \leq kT} \phi_n(\beta x) \). This is a decreasing function in \( |x| \); moreover, by Lemma 4.3.2 in Lawler and Limic (2007), it equals \( C_1/|x|^{d-2} + O(1/|x|^{d+2}) \) as \( |x| \to \infty \) for some \( C_1 > 0 \). Secondly, for all \( k \) sufficiently large and all \( |x| \leq A \sqrt{k} \),

\begin{equation}
\sum_{n \leq kT} P_n(x) \geq \sum_{kT/2 \leq n \leq kT} P_n(x) \geq \sum_{kT/2 \leq n \leq kT} n^{-d/2} C \geq C k^{1-d/2};
\end{equation}
note further that
\[ \sum_{n>kT} P_n(x) \leq C \sum_{n>kT} n^{-d/2} \leq C k^{1-d/2}; \]
therefore there exists \( \delta > 0 \) such that all \( k \) sufficiently large and all \( |x| \leq A \sqrt{k} \),
\[ \sum_{n\leq kT} P_n(x) \geq \delta \sum_{n=1}^\infty P_n(x). \]

For the nearest neighbor random walk, \( \sum_{n=1}^\infty P_n(x) \) equals \( C_2/|x|^{d-2} + O(1/|x|^{d+2}) \) as \( |x| \to \infty \) for some \( C_2 > 0 \). Relation (19) follows.

**Proof of (19) when \( d = 2 \).** In this case, one can deduce from the proof of Theorem 4.4.3 in Lawler and Limic (2007) that there exist \( C_i > 0, i = 1, 2, 3, 4 \) such that for all \( |x| \leq A \sqrt{k} \),
\[ \sum_{n\leq kT} \phi_n(\beta x) \asymp C_1 + C_2 \log(kT/|x|^2), \]
and
\[ \sum_{n\leq kT} P_n(x) \asymp C_3 + C_4 \log(kT/|x|^2). \]
(19) follows.

To complete the proof of Lemma 2, it remains to prove inequality (18).

**Proof of (18).** By (17), it suffices to show that there exists \( C > 0 \) such that for all \( x \in \mathbb{Z}^d \) and all \( i, j \in \mathbb{N} \),
\[ \sum_y \phi_i(\beta y) \phi_j(\beta(x-y)) \leq C \phi_{i+j}(\beta x/2). \]
For all \( y \in \mathbb{Z}^d \), Let \( Q_y \) be the cube centered at \( y \) with length 1, and define
\[ \tilde{\phi}_i(y) = \int_{z \in Q(y)} (2\pi i/\beta^2)^{-d/2} \exp(-\beta^2 |z|^2/(2i)) \, dz. \]
Then there exists \( C > 0 \) such that for all \( i \) and all \( x \),
\[ \phi_i(\beta x) \leq C \tilde{\phi}_i(x). \]
Therefore to show (71), it suffices to show that there exists \( C > 0 \) such that for all \( x \in \mathbb{Z}^d \) and all \( i, j \in \mathbb{N} \),
\[ \sum_y \tilde{\phi}_i(y) \tilde{\phi}_j(x-y) \leq C \phi_{i+j}(\beta x/2). \]
Note \( (\tilde{\phi}_i(\cdot)) \) is the probability mass function of the random variable \([\Lambda_i]\), where \( \Lambda_i \sim N(0, i/\beta \cdot I_d) \), and for any \( z \in \mathbb{R}^d \setminus \cup_y \partial Q(y) \), \([z]\) is the unique \( y \) such that \( z \in Q(y) \) (\( \Lambda_i \) takes values on \( \cup_y \partial Q(y) \) with probability 0, so \([\Lambda_i]\) is well defined a.s.). Hence \( \sum_y \phi_i(y) \phi_j(\cdot - y) \) is the probability mass
function of \([\Lambda_i] + [\Lambda_j]\) with \(\Lambda_i\) and \(\Lambda_j\) being independent. Since \([\Lambda_i] + [\Lambda_j]\) differs from \(\Lambda_i + \Lambda_j\) by at most 2,

\[
\sum_y \phi_i(y) \phi_j(x - y) \leq \int_{|z - x| \leq 2} (2\pi(i + j)/\beta^2)^{-d/2} \exp(-\beta^2|z|^2/(2(i + j))) dz.
\]

It is easy to see that the last term can be bounded by \(C\phi_{i+j}(\beta x/2)\) for some \(C\) independent of \(i, j\) and \(x\).

\[\square\]

4.2. **Proof of Lemma 4**. By the monotonicity of \(\phi_n(x)\) in \(|x|\), for all integers \(m, l \geq 1\) and all \(x, y \in \mathbb{R}^d\) we have

\[
\phi_m(x)\phi_l(y) \leq \phi_m(x)\phi_l(x) + \phi_m(y)\phi_l(y) \leq C(ml)^{-d/4}(\phi_{ml/(m+l)}(x) + \phi_{ml/(m+l)}(y)).
\]

Now note that for any \(t > 0\) and any \(x\),

\[
\phi_t(x) = (2\pi t)^{-d/2} \exp(-|x|^2/(2t)) \leq 2^{d/2} \cdot 2t(x),
\]

and when \(t \geq 1\),

\[
\phi_t(x) \leq \phi_{[t]}(x) \cdot ([t]/t)^{d/2} \leq 2^{d/2} \phi_{[t]}(x),
\]

where \([t]\) stands for the smallest integer bigger than or equal to \(t\). Further note that when \(m, l \geq 1\), \(ml/(m + l) \geq 1/2\). Using the two inequalities above we then get

\[
(73) \quad \phi_m(x)\phi_l(y) \leq C(ml)^{-d/4} \left(\phi_{[2ml/(m+l)]}(x) + \phi_{[2ml/(m+l)]}(y)\right).
\]

and

\[
\Phi_m(x, y)\Phi_l(u, v) = \phi_m(x)\phi_l(u) + \phi_m(x)\phi_l(v) + \phi_m(y)\phi_l(u) + \phi_m(y)\phi_l(v) \leq C(ml)^{-d/4} \left(\Phi_{[2ml/(m+l)]}(x, y) + \Phi_{[2ml/(m+l)]}(u, v)\right)
\]

Therefore for all \(h_1, h_2 \geq 1\),

\[
F_{n, h_1}(x, y; \beta) F_{n, h_2}(x, y; \beta) = \sum_{|\rho_1| < h_1} \sum_{|\rho_2| < h_2} \sum_{m < n} \sum_{l < n} (ml)^{-\gamma/2} \Phi_m(\beta(x + \rho_1), \beta(y + \rho_1)) \cdot \Phi_l(\beta(x + \rho_2), \beta(y + \rho_2)) \leq \sum_{|\rho| < h_1 + h_2 - 1} \sum_{m < n} \sum_{l < n} C(ml)^{-d/4-\gamma/2} \cdot \left\{\Phi_{[2ml/(m+l)]}(\beta(x + \rho_1), \beta(y + \rho_1)) + \Phi_{[2ml/(m+l)]}(\beta(x + \rho_2), \beta(y + \rho_2))\right\} \leq \sum_{|\rho| < h_1 + h_2 - 1} \sum_{m < n} C(ml)^{-d/4-\gamma/2} \Phi_{[2ml/(m+l)]}(\beta(x + \rho), \beta(y + \rho)).
\]

\[\square\]
Observe that when \( m, l \in [1, n) \), \( ml/(m+l) \in [1/2, n/2) \), hence the last term is bounded by
\[
C n^{2-(d+2\gamma)/2} \sum_{|\rho|<h_1+h_2-1} \cdot \sum_{l<n} \Phi_l(\beta(x+\rho), \beta(y+\rho))
\]
\[
\leq C n^{2-(d+\gamma)/2} \sum_{|\rho|<h_1+h_2-1} \cdot \sum_{l<n} l^{-\gamma/2} \Phi_l(\beta(x+\rho), \beta(y+\rho))
\]
\[
= C n^{2-(d+\gamma)/2} F_{n,h_1+h_2-1}(x,y;\beta),
\]
i.e., (23) holds.

We now prove (24). By (74),
\[
\sum_{i<n} \sum_{z} P_i(z) \cdot [F_{n-i,h_1}(x-z,y-z;\beta) F_{n-i,h_2}(x-z,y-z;\beta)]
\]
\[
\leq \sum_{i<n} \sum_{z} P_i(z) \sum_{|\rho|<h_1+h_2-1} \sum_{m-n-i<l<n-i} \cdot C(ml)^{-d/4-\gamma/2} \Phi|_{2ml/(m+l)} (\beta(x-z+\rho), \beta(y-z+\rho))
\]
\[
\leq \sum_{m<n} \sum_{l<n} C(ml)^{-d/4-\gamma/2} \sum_{|\rho|<h_1+h_2-1} \sum_{i<\min(n-m,n-l)} \cdot P_i(z) \Phi|_{2ml/(m+l)} (\beta(x-z+\rho), \beta(y-z+\rho)).
\]

Using relation (18) and noting that \( \lfloor 2ml/(m+l) \rfloor \leq \max(m,l) \), we can further bound the last term by
\[
C n^{2-(d+2\gamma)/2} \sum_{|\rho|<h_1+h_2-1} \cdot \sum_{l<n} \Phi_l(\beta(x+\rho)/2, \beta(y+\rho)/2)
\]
\[
\leq C n^{2-(d+\gamma)/2} F_{n,h_1+h_2-1}(x,y;\beta/2).
\]

4.3. Proof of Lemma 5  For all \( h_1, h_2 \geq 1 \), all \( x \in \mathbb{Z}^d \) and all integers \( m, n \geq 1 \), by (73),
\[
J_{m,n,h_1}(x;\beta) J_{m,n,h_2}(x;\beta)
\]
\[
= \sum_{|\rho_1|<h_1} \sum_{|\rho_2|<h_2} \sum_{m\leq l_1,l_2 \leq m+n} \phi_{l_1}(\beta(x+\rho_1)) \phi_{l_2}(\beta(x+\rho_2))
\]
\[
\leq C \sum_{|\rho_1|<h_1} \sum_{|\rho_2|<h_2} \sum_{m\leq l_1,l_2 \leq m+n} \cdot (l_1 l_2)^{-d/4} \{ \phi|_{2l_1l_2/(l_1+l_2)} (\beta(x+\rho_1)) + \phi|_{2l_1l_2/(l_1+l_2)} (\beta(x+\rho_2)) \}\}
\]
\[
\leq C \sum_{|\rho|<h_1+h_2-1} \sum_{m\leq l_1,l_2 \leq m+n} (l_1 l_2)^{-d/4} \phi|_{2l_1l_2/(l_1+l_2)} (\beta(x+\rho)).
\]

Note that when \( l_1, l_2 \in [m, m+n) \), \( [2l_1/2 + l_2) \in [m, m+n) \), hence the last term is bounded by
\[
C n^{2-d/2} \sum_{|\rho|<h_1+h_2-1} \sum_{m\leq l \leq m+n} \phi_l(\beta(x+\rho)) = C n^{2-d/2} J_{m,n,h_1+h_2-1}(x;\beta),
\]
i.e., \((26)\) holds.

We now prove \((27)\). By \((75)\),
\[
\sum_{i<n} \sum_z P_i(z) \cdot (J_{m,n-i,h_1}(x-z; \beta) J_{m,n-i,h_2}(x-z; \beta))
\leq \sum_{i<n} \sum_z P_i(z) \sum_{|\rho|<h_1+h_2-1} \sum_{m\leq l_1 l_2 \leq m+n-i} C(l_1 l_2)^{-d/4} \phi[2l_1 l_2/(l_1+l_2)](\beta(x-z+\rho))
\leq \sum_{m\leq l_1 l_2 \leq m+n} C(l_1 l_2)^{-d/4} \sum_{|\rho|<h_1+h_2-1} \sum_{i<\min(m+n-l_1,m+n-l_2)} P_i(z) \phi[2l_1 l_2/(l_1+l_2)](\beta(x-z+\rho)).
\]

Using relation \((18)\) and noting that \([2l_1 l_2/(l_1 + l_2)] \in [\min(l_1, l_2), \max(l_1, l_2)]\), we can further bound the last term by
\[
C n^{2-d/2} \sum_{|\rho|<h_1+h_2-1} \sum_{m\leq i<m} \phi_i(\beta(x+\rho)/2) = C n^{2-d/2} J_{m,n,h_1+h_2-1}(x; \beta/2).
\]

\[\square\]
