**N-body Efimov states from two-particle noise**

Amy N. Nicholson

Maryland Center for Fundamental Physics, Department of Physics, University of Maryland, College Park MD 20742-4111

The ground state energies of universal $N$-body clusters tied to Efimov trimers, for $N$ even, are shown to be encapsulated in the statistical distribution of two particles interacting with a background auxiliary field at large Euclidean time when the interaction is tuned to the unitary point. Numerical evidence that this distribution is log-normal is presented, allowing one to predict the ground-state energies of the $N$-body system.

While noisy correlators are generally regarded as an impediment for Monte Carlo calculations, there is often a physical mechanism underlying the appearance of noise. Understanding the form of the statistical distribution can lead not only to better methods for extracting reliable quantities from numerical calculations, but also to insight into the physics itself. In this work, we illustrate this principle using a correlator for two particles with an interaction tuned to give a bound state at threshold, called the unitary point. From the distribution of this correlator we are able to extract the energies of 2$N$-body Efimov states, deeply bound universal systems of bosons or distinguishable fermions tuned to unitarity, which are tied to Efimov trimers [1, 2]. Efimov physics has enjoyed a resurgence of interest among the atomic, nuclear, and condensed matter communities due to advances in ultracold atom experiments, particularly with recent experimental evidence for three- and four-body Efimov states displaying universal characteristics [3–8], meaning their low-energy behavior is independent of the details of the interaction. However, theoretical information about the existence and properties of higher-body systems has been limited to that from direct measurements of $N$-body states using non-perturbative numerical methods [9–12].

Recent lattice studies of many-fermion systems at unitarity have shown that the correlators display distributions with log-normal characteristics [13–14]. Using our two-body correlator we establish a deep connection between Efimov physics and the log-normal distribution. We then present lattice data which indicates that the two-body correlator we establish a deep connection between Efimov physics and the log-normal distribution. Finally, we compare our results to those from numerical calculations.

To begin, we will define the two-body correlation function of interest and study its distribution by calculating the moments. The Lagrangian consists of two flavors of fermions $\psi$, the interaction with coupling $\kappa$,

$$\mathcal{L} = \psi^\dagger (\partial_\tau - \nabla^2/2M) \psi + \kappa^2 (\psi^\dagger \psi)^2.$$  

Performing a Hubbard-Stratonovich transformation gives the Euclidean path integral in terms of an auxiliary field, $\phi$,

$$Z = \int \mathcal{D}\psi^\dagger \mathcal{D}\psi \mathcal{D}\phi e^{-\int d\tau d^3x (\psi^\dagger K \psi + \frac{1}{2} \phi^2)},$$

$$K = (\partial_\tau - \nabla^2/2M) + \kappa \phi.$$  

The two-particle correlation function is given by

$$C_2(T) = \langle \Psi(T) \Psi^\dagger(0) \rangle,$$  

where

$$\Psi(\tau) = \int dx_1 dx_2 A(x_1, x_2) \psi^\dagger(x_1, \tau) \psi(x_2, \tau).$$  

annihilates a two-body state, with wavefunction $A$ at time $\tau$, which has non-zero overlap with the two-body ground state. Integrating out the $\psi$ fields gives the correlation function as a path integral over $\phi$ field configurations only,

$$C_2(T) = \langle C_2(\phi, T) \rangle_\phi = \frac{1}{Z_\phi} \int \mathcal{D}\phi (\det K)^2 S_2(\phi, T) e^{-\int d\tau d^3x \frac{1}{2} \phi^2},$$

$$Z_\phi = \int \mathcal{D}\phi (\det K)^2 e^{-\int d\tau d^3x \frac{1}{2} \phi^2},$$  

where $S_2(\phi, T)$ is the two-particle propagator from Euclidean time $\tau = 0$ to $T$ on a given background field, $\phi$, and we have one power of $\det K$ for each flavor. Using open temporal boundary conditions, one may show that $\det K$ is a constant independent of $\phi$, and therefore may be disregarded [15]. The use of open boundary conditions is justified so long as we restrict our arguments to zero temperature (large Euclidean time).

By inserting a complete set of energy eigenstates, $|n\rangle$, in Eq. [3] one may show that for large Euclidean time, $T$, $C_2$ will be dominated by the ground state,

$$C_2(T) = \sum_n \langle \Psi(0)|n\rangle e^{-E_0^{(2)}T} \langle n|\Psi(0) \rangle \xrightarrow{T \to \infty} Z_2 e^{-E_0^{(2)}T},$$  

where $E_0^{(2)}$ is the ground state energy of the two-body system and $Z_2$ gives the overlap of the operator $\Psi$ with the ground state.

---

*Electronic address: amynn@umd.edu*
Following an argument of Lepage \[10\], we determine the second moment of the correlator as follows,
\[
\mathcal{M}_2(T) = \left\langle (|C_2(\phi,T)|^2)_{\phi}\right\rangle = \frac{1}{Z_0} \int D\phi (S_2[\phi,T])^2 e^{-\int dtd^3x \frac{1}{2} \phi^2}.
\]
(7)

We see that this quantity is just the correlator for two 2-body propagators, corresponding to the four-particle system. Because there is no (anti-)symmetrization between the four (fermions) bosons, each particle must correspond to a different flavor. In order to properly describe a four-flavor theory we should also require four powers of det $K$ in the partition function, Eq. 5. However, because det $K$ is a constant in our formulation, the partition function is unchanged when the number of flavors is increased.

For the large Euclidean time limit we have,
\[
\mathcal{M}_2(T) \to Z_4 e^{-E_0^{(4)} T},
\]
(8)
where $E_0^{(4)}$ is the ground state energy of the four-particle, four-flavor system, and $Z_4$ gives the overlap of $\Psi^4$ with the four-particle ground state. We may generalize this argument for all moments,
\[
\mathcal{M}_N(T) \to Z_{2N} e^{-E_0^{(2N)} T},
\]
(9)
where $E_0^{(2N)}$ is the ground state energy of the $2N$-particle system in the $2N$-flavor theory and $Z_{2N}$ represents the overlap of $\Psi^N$ with the $2N$-particle ground state, which is assumed to be non-zero but may be arbitrarily small.

Let us now consider the ground-state of these systems in the unitary limit, where the two-body ground-state energy is zero by construction. The three-body system exhibits the well-known Efimov effect \[1, 2\], consisting of a series of bound trimers whose energies are separated by a factor of $\sim 515$. The ground-state is stabilized against collapse by an effective 3-body interaction which becomes relevant for low energy physics. Hence, the addition of a third particle to the conformally invariant two-particle system introduces an energy scale, $\Lambda_E$, to which the 3-body ground-state binding energy may be related, $E_0^{(3)} = -a_3 \Lambda_E$. Theoretical studies \[9, 10, 17, 20\] as well as recent experiments \[7, 8\] indicate that the spectrum of the four-body, four-flavor theory consists of a set of two bound tetraneurals tied to each Efimov trimer. Provided the UV physics is fixed such that the ground state is sufficiently far from the cutoff, the ratio of the lowest four-body state to the lowest Efimov trimer has been shown to be universal constant \[9, 10, 17, 19, 20\]. This implies that there is no relevant four-body scale for this system, so $\Lambda_E$ remains the only scale, giving $E_0^{(4)} = -a_4 \Lambda_E$.

One may postulate that no new relevant scales will emerge for the $N$-body system at unitarity, and numerical evidence for up to $N = 40$ suggests that this is true \[9, 10, 12\]. Accordingly, the energy of the $N$-body system will be $E_0^{(N)} = -a_N \Lambda_E$.

Returning to the probability distribution, we may combine the above relation between energies at unitarity with the moments of the distribution, giving
\[
\mathcal{M}_N^{\text{unit}}(T) \to Z_{2N} e^{a_{2N} \Lambda_E T}
\]
(10)

Now we shall discuss the observed behavior of the distribution using lattice results. In \[13\] it was shown that lattice calculations of strongly interacting non-relativistic systems tend to display heavy-tailed distributions at large Euclidean time. In particular, it was found that the distributions are approximately log-normal (LN), i.e. that the logarithm of the quantity of interest obeys the normal distribution. It was also shown that an expansion around LN, called the cumulant expansion, can be used to extract a reliable mean for the correlator. Using this method, the moments of $\ln C$ are calculated and the correlator is given by $C(T) = \lim_{N_e \to \infty} \ln C^{(N_e)}(T)$, where
\[
\ln C^{(N_e)}(T) \equiv \sum_{n=1}^{N_e} \frac{\kappa_n(T)}{n!}.
\]
(11)

Here, $\kappa_n(T)$ is the $n$-th cumulant of the distribution for $\ln C(\phi,T)$, and the expansion may be cut off for finite $N_e$ provided the distribution is close enough to LN that the series converges. For the LN distribution, $\kappa_n = 0$ for $n \geq 3$, so the expansion may be cut off exactly at $N_e = 2$.

A histogram of the two-particle correlator at unitarity is shown in Fig. 11 for large Euclidean time. The distribution of the logarithm of the correlator is also shown in the inset. The data was generated using the lattice method developed in \[15\]. A set of momentum-dependent interactions are tuned to systematically correct for lattice artifacts, bringing us closer to the unitary point by effectively setting the range of the interaction and the first few shape parameters to zero. Preliminary calculations have shown that an $L = 16$ box is sufficient to eliminate finite volume effects for the three-body state \[21\], which is the largest of the $N$-body bound states and therefore most susceptible to finite volume errors. Finally, there is a hard momentum cutoff in our formulation. We find that in the absence of an explicit three-body interaction the resulting energy cutoff is approximately $335$ times the three-particle ground-state energy per particle.

We see that this correlator exhibits a very heavy tail, while the logarithm of the correlator appears to be Gaussian, characteristic of the LN distribution. To understand physically why this occurs, let us compare the moments derived above to those of the LN distribution. For the LN distribution the $n$-th moment is
\[
\mathcal{M}_n^{\text{LN}} = e^{\mu \frac{1}{2} \sigma^2}
\]
(12)
where $\mu, \sigma$ are the mean and standard deviation, respectively, of the logarithm of the correlator.

We may extract values for these parameters by setting Eq. 9 equal to Eq. 12 for $n = N = 1$ and $n = N = 2$ to find $\mu = \frac{1}{2} E_0^{(4)} T, \sigma^2 = -E_0^{(4)} T$. Thus, for the special
The moments become, only one scale controlling all moments of the distribution. σ are no longer independent. This implies that there is

We see that the N relator is exactly LN, we can deduce the energies of all higher moments. Should be LN in the absence of further constraints on the case of unitarity, where E(2) = 0, we find that μ and σ are no longer independent. This implies that there is only one scale controlling all moments of the distribution. The moments become,

\[ \mathcal{M}_n^{\text{LN}} \propto e^{-\frac{1}{2} n(n-1) E^{(4)}_{\text{eff}} T} = e^{\frac{1}{2} n(n-1) \alpha \Lambda E T} . \] (13)

A comparison of Eq. [10] and Eq. [13] shows that the moments given by the LN distribution display the same scaling behavior with ΛE, T as the moments predicted by the Efimov spectrum. Therefore, systems in which the Efimov effect plays a role are likely to have distributions with LN characteristics. In turn, having a LN distribution implies an infinite tower of universal N-body states whose energies are proportional to a single scale. Note that the LN distribution is the maximum entropy distribution of its class: once the parameters μ and σ have been fixed by the energies E(2) and E(4), the distribution should be LN in the absence of further constraints on the higher moments.

Finally, assuming the distribution of the two-body correlator is exactly LN, we can deduce the energies of all 2N-body states by equating Eq. [9] with Eq. [13]

\[ E^{(2N)}_0 = \frac{1}{2} N(N-1) E^{(4)}_0 \] (14)

We see that the N-dependence of the energy relation is equivalent to the number of pairwise interactions between dimers.

For an approximately LN distribution one could imagine systematically improving this relation by numerically calculating third and higher cumulants of ln C2, using this information to correct the distribution, for example via the principle of maximum entropy, and recalculating the moments of C2. We would like to emphasize that this approach does not simply translate a difficult many-body problem into an equally difficult problem of extracting large moments of a distribution, but rather small moments of ln C2.

Remarkably, to within a few percent, we find that the distribution is indeed LN. In Fig. 2 (green points) we plot the cumulant expansion for the lattice data. Recall that for the LN distribution, this expansion converges at Nc = 2. Thus, the discrepancy between the expansion cut off at Nc = 2 and the result after convergence may be used to quantify how close to LN a distribution is. We find that our lattice data is LN to within ~ 2%. This small discrepancy is likely due to the finite time extent used and sensitivity to lattice artifacts for large moments of C2.

The energies for an exactly LN distribution (Eq. [14]) are plotted in Fig. 3 along with results from a numerical calculation employing a model potential. Comparing with [11], we find agreement at the 10 – 30% level, with greater discrepancy for larger N.

The inset shows the results for E0/E4 from three separate numerical calculations, [9], [10], and [11]. The three points from left to right represent a movement toward a more universal regime (see details in [10] [11]). One sees a trend toward the LN result as the universal regime is reached. For larger N, universality may be increasingly difficult to reach in numerical calculations as the more compact states begin to probe the details of the potential model used in these calculations.

One may ask by how much we can deform the relation between energies and still recover a distribution that is LN in appearance. In particular, could the small discrepancy from LN seen in the lattice data give the 10 – 30% shift in energies corresponding to those in [10]?

To answer this question, we created mock distributions by expanding about a LN distribution and fitting the undetermined coefficients so that the moments gave the energies calculated in [10]. We created several of these distributions, using different parameterizations and fitting different combinations of energies. The results for the cumulant expansion, Eq. [11], of one of the mock distributions is plotted in Fig. 2 along with that for the lattice data of the two-body correlator. We find that the discrepancy for all mock distributions is ~ 17% - 30%, which is comparable to the difference in energies from the LN distribution and those of [10]. We conclude that the energies implied by our two-particle correlator should be those of Eq. [14] likely to within a few percent.

The LN distribution implies other physical consequences that connect this distribution with universal behavior. If we begin by choosing a wavefunction for our source that corresponds exactly to the solution for the two-body system, then Z2 = 1 and the constant of proportionality in Eq. [13] is,

\[ Z_{2N} = Z_2^{\frac{1}{2} N(N-1)} \] (15)

We may interpret this relation as implying that the size of the system, and therefore the overlap, scales with N in the same way as the energy.

Finally, note that if the two-body correlator is LN, then by extension the correlators for all 2N-body Efimov states will also be LN, with rescaled parameters μ and σ2. The logarithm of the sth moment for the 2N-body
correlator is given by the energy relation, Eq. (14)

\[ E_0^{(2N_s)T} = \frac{1}{2} N s (N s - 1) E_0^{(4)T}. \]  

Comparing to the moments of the LN distribution (Eq. 12), we find \( \mu = \frac{1}{2} N E_0^{(4)T}, \sigma^2 = -N^2 E_0^{(4)T} \).

For odd numbers of particles, the correlator is not positive so a LN distribution is not expected. However, in practice it is found that these distributions are approximately LN with a small negative contribution. By fixing an additional ratio, such as \( E_4/E_3 \), one may extract approximate relations between the energies for odd systems.

To summarize, a connection between the log-normal distribution and Efimov physics has been established using the distribution of the two-body correlator at unitarity. Using this connection, a novel method for obtaining the ground-state energies of \( 2N \)-body Efimov states has been introduced. Because lattice data strongly indicates that the distribution of this correlator is LN to within a few percent, we calculate the expected ground-state energies from the moments of the LN distribution.

We note that the scaling of the energy per particle given by the LN distribution, \( E_0^{(N)}/N \sim \frac{1}{2} N \), implies that cutoff independence should not hold for arbitrarily large \( N \). Thus, very large moments of the distribution are not expected to conform to those of the LN distribution. However, these moments correspond to the non-universal regime which is inherently of less interest than the universal regime for which the LN distribution appears to be relevant.

Given that the distribution is likely not exactly LN due to these large moments, analytical progress may be made by developing a perturbative expansion around LN, perhaps in the spirit of the semiclassical expansion introduced in [13]. Numerical efforts to reduce systematics in the lattice calculation of the moments of \( \ln C_2(\phi) \) would help to sort out true deviations from LN from lattice artifacts, and any true deviations may be included in the overall distribution to obtain improved results for the energies.
