Abstract: The unified stochastic particle method based on the Bhatnagar-Gross-Krook model (USP-BGK) has been proposed recently to overcome the low accuracy and efficiency of the traditional stochastic particle methods, such as the direct simulation Monte Carlo (DSMC) method, for the simulation of multi-scale gas flows. However, running with extra virtual particles and space interpolation, the previous USP-BGK method cannot be directly transplanted into the existing DSMC codes. In this work, the implementation of USP-BGK is simplified using new temporal evolution and spatial reconstruction schemes. As a result, the present algorithm of the USP-BGK method is similar to the DSMC method and can be implemented efficiently based on any existing DSMC codes just by modifying the collision module.

Keywords: Multiscale flows, Stochastic particle method, Kinetic model

1. Introduction

Multi-scale gas flows widely exist in aerospace engineering [1] and micro-electro-mechanical systems (MEMS) [2]. Due to the invalidity of the continuous methods in the rarefied regime and the inefficiency of the kinetic methods in the continuum regime, it is challenging for the traditional numerical methods to simulate multi-scale gas flows accurately and efficiently. One of the strategies to overcome this difficulty is combining the continuous and kinetic methods. For example, the CFD-DSMC hybrid method [3-5] implements the CFD solver and direct simulation Monte Carlo (DSMC) method in different regions. Another example is the general synthetic iterative scheme (GSIS) [6] developed recently, which is solved by the CFD and discrete velocity method (DVM) together in the whole region but at different levels. The hybrid methods need to exchange the information between different solvers, which will bring extra complexity even stability problem [7]. Therefore, besides the hybrid methods, a straightforward
approach is to extend the application of the kinetic methods to the continuum regime. Following this direction, many multi-scale schemes based on kinetic models, such as Bhatnagar–Gross–Krook (BGK) [8-10] and Fokker-Planck (FP) [11-13], have been proposed in recent decades. One of the categories is the deterministic DVM methods with asymptotic preserving (AP) property, such as the BGK-type penalization method [14], the implicit-explicit (IMEX) method [15,16], the unified gas-kinetic scheme (UGKS) [17] and the discrete unified gas kinetic scheme [18]. However, representing the probability density function (PDF) with discrete velocities requests a large memory consumption, especially for hypersonic gas flows. An alternative category is the stochastic particle methods, such as the BGK particle method [19] and the Fokker-Planck particle method [20]. Unlike DVM, stochastic particle methods describe the PDF using simulation particles, of which each represents a large number of real gas molecules of a certain velocity. Since the distribution of computational particles can adaptively be refined in the velocity space, the curse of dimensionality is circumvented compared to the DVM method.

As decoupling the particle motion and collision in most stochastic particle methods, they only asymptotically preserve the Euler limit. For example, considering the traditional stochastic particle BGK (SP-BGK) method [8, 19], when the time step is much larger than the mean collision time, its numerical viscosity is of the first order of the time step, i.e. $\mu_{\text{BGK}}^{\text{num}} \sim \Delta t$. An important exception is the Fokker-Planck particle method, for which particle motion and collisions can be solved simultaneously [11]. When the time step is much larger than the mean collision time, its numerical viscosity $\mu_{\text{FP}}^{\text{num}}$ converges to $2\mu$, where $\mu$ is the gas viscosity, that is, independent of the time step [13]. Therefore, the Fokker-Planck particle method could asymptotically preserve the Navier-Stokes limit.

Recently, a unified stochastic particle method preserving the Navier-Stokes limit based on the BGK model, which is referred to as the USP-BGK method, has also been developed [21] by combining a modified continuous collision term with particle motions. It has been demonstrated by a variety of gas flows [21, 30] that with the
Crank–Nicolson scheme in the particle motion step, the USP-BGK method has a second-order accuracy in the continuum regime. In the aspect of implementation, the USP-BGK method is quite similar to the other particle methods such as DSMC. However, to involve the collision effect in the process of particle motions, virtual particles need to be introduced. In addition, to make the spatial accuracy consist with the temporal accuracy, a second-order interpolation in space is employed to obtain the mean quantities related to the individual particle. Since these two aforementioned procedures are not contained in the original DSMC method, transplanting the USP-BGK method into the existing DSMC program code is not straightforward. To make the principle of USP-BGK easier to be understood and minimize the difference of implementation between USP-BGK and DSMC, an efficient algorithm of USP-BGK is developed in the present work.

The remainder of this paper is organized as follows. In section 2, we first review the principle and the solution algorithm of the unified stochastic particle BGK method. Then, the temporal evolution and spatial reconstruction of the efficient algorithm is introduced in section 3. Note that the simplified time scheme without virtual particles was already developed in the hybrid USPBGK-DSMC method [22]. Here we present a sole USP-BGK version for the sake of clarity. In section 4, we provide numerical results for several typical gas flows, and the accuracy of the proposed method is also validated.

2. Review of the USP-BGK method

The BGK model simplifies the Boltzmann collision term using a relaxation process. In general, its dimensionless kinetic equation can be written as

\[ \frac{\partial f}{\partial t} + c_i \frac{\partial f}{\partial x_i} = \frac{1}{\epsilon} (f_i - f) , \]

where \( f(c;\mathbf{x},t) \) is the weighted probability density function, which is defined as

\[ n = \int f(c;\mathbf{x},t) \, dc \]  

\( n \) is the number density, and \( \mathbf{c} \) is the molecule velocity at position \( \mathbf{x} \) and time \( t \). The subscript \( i \) indicates the \( i \)-th component in three-dimensional space. \( f_i \) is a target distribution function for the relaxation process [19]. In the original
BGK model, \( f_t \) is assumed to be the Maxwellian distribution function, i.e.

\[
f_t = f_m = n \left( \frac{2}{\pi} \right)^\frac{3}{2} \exp \left( -\frac{4C^2}{\pi T} \right)
\]  

(2)

where \( C = \mathbf{e} \cdot \mathbf{U} \) is the peculiar molecular velocity, \( \mathbf{U} \) is the mean velocity, and \( T \) is temperature. The Prandtl number (\( Pr \)) of the original BGK model is always unity for any gas flows. To correct the Prandtl number, the Shakhov [23] (SBGK) and ellipsoidal statistical [24] (ESBGK) BGK models are usually applied. Non-dimensional variables used in the present paper are defined as,

\[
\hat{x} = \frac{x}{x_*}, \quad \hat{n} = \frac{n}{n_*}, \quad \hat{C} = \frac{c}{C_*}, \quad \hat{t} = \frac{t}{x_*/C_*}, \quad \hat{f} = \frac{f}{n_*/C_*^3},
\]

(3)

where \( x_* \) and \( n_* \) are the reference length and number density, respectively, \( C_* = \sqrt{8RT_*/\pi} \) is the mean thermal reference velocity and \( T_* \) is the reference temperature. \( R = k_b/m \) is the gas constant, \( m \) is the molecular mass, \( k_b \) is the Boltzmann constant. Therefore, the Knudsen number \( \varepsilon \) is defined as \( \varepsilon = \tilde{C}/(\nu_{bgk} x_*) \), where \( \nu_{bgk} = p/\mu \) is the collision frequency of the BGK model, \( \mu \) is the gas viscosity and \( p \) is the pressure. For the sake of simplicity, all the equations, unless specified differently, will be presented in the dimensionless form without hats on top of the variables.

The BGK equation can be either solved using the DVM [25] or stochastic particle [8] methods. Similar to DSMC, the traditional SP-BGK method [19] decouples the particle motion and collision, i.e., the BGK equation is numerically solved in sequence,

\[
\frac{\partial f}{\partial t} + c \frac{\partial f}{\partial x} = 0 \quad \text{and}
\]

\[
\frac{\partial f}{\partial t} + \frac{1}{\varepsilon} \left( f_t - f \right).
\]

(4a) \hspace{1cm} (4b)

Decoupling the particle motion and collision is easily and naturally implemented in the stochastic particle methods. Note that the particle motion step as shown in Eq. (4a) is represented by a collisionless kinetic equation, so if the time step is larger than the mean collision time, its numerical dissipation is of the first order of the time step size. To
extend the applicability of the SP-BGK method, a unified stochastic particle method based on the BGK model (USP-BGK) has been proposed recently [21]. Similarly, the USP-BGK method also consists of particle motion and collision steps, i.e.

\[
\frac{\partial f}{\partial t} + c_i \frac{\partial f}{\partial x_i} = J'_{\text{(USP-BGK)}} \quad \text{and} \quad \frac{\partial f}{\partial t} = \frac{1}{\varepsilon} (f_f - f) - J'_{\text{(USP-BGK)}},
\]

(5a) (5b)

The key difference is that the collision term in the USP-BGK method is divided into two parts, and the continuous part is calculated with particle motion simultaneously. For monoatomic gas, the continuous part \( J_{\text{(USP-BGK)}} \) is closed by the 13 moments Grad’s distribution function \( f_{\text{Grad}} \), i.e.

\[
J_{\text{(USP-BGK)}} = \frac{P_c}{\varepsilon} (f_M - f_{\text{Grad}}) = -\frac{P_c}{\varepsilon} \left[ \frac{\sigma_{ij}}{2\rho T^2} \left( \frac{8}{\pi} \right) C_{ij} C_{j>}, + \frac{2q_i C_{j>}}{5\rho T^2} P_F \left( \frac{8}{\pi} \right) \left( \frac{4C_i^2}{\pi T} - \frac{5}{2} \right) \right] f_M,
\]

(6)

where \( \rho \) is the density, \( \sigma_{ij} \) is the shear stress, and \( C_{ij} C_{j>}, \) denotes the symmetric and trace-free part of the tensor \( C_{ij}. \) The multi-scale parameter \( P_c, \) which denotes the degree of the continuum, tends to 1 in the continuum regime and 0 in the rarefied regime. In reference [21], \( P_c \) is assumed as

\[
P_c = e^{-K_{\text{Kn}}/K_{\text{Kn}_{\text{MAX}}}},
\]

(7)

where \( K_{\text{Kn}} \) is a reference Knudsen number, and \( K_{\text{Kn}_{\text{MAX}}} \) is the maximum value of the gradient-length local (GLL) Knudsen number suggested by Wang and Boyd [26]. Therefore, with small Knudsen numbers, the particle motion step as shown in Eq. (5a) is represented by a first-order Chapman-Enskog expansion of the BGK equation and converges to the NS limit.

For the particle motion step as shown in Eq. (5a), to obtain a second-order of accuracy in time, it is numerically solved with the Crank–Nicolson scheme, i.e.

\[
f'(\mathbf{c}, \mathbf{x}, \Delta t) = \frac{\Delta t}{2} \left[ J'_{\text{(USP-BGK)}}(\mathbf{c}, \mathbf{x}, \Delta t) + J'_{\text{(USP-BGK)}}(\mathbf{c}, \mathbf{x} - c \Delta t, 0) \right] + f(\mathbf{c}, \mathbf{x} - c \Delta t, 0),
\]

(8)

with the initial condition \( f'(\mathbf{c}, \mathbf{x}, 0) = f(\mathbf{c}, \mathbf{x}, 0). \) By introducing two auxiliary PDFs [18]
\[ f^* = f^* - \frac{\Delta t}{2} J_{\text{USPBGK}}, \quad \text{and} \]
\[ f = f + \frac{\Delta t}{2} J_{\text{USPBGK}}. \]  
Eq. (8) can be rewritten as
\[ f^* (c, x, \Delta t) = f (c, x - c\Delta t, 0). \]  
Therefore, \( f^* (c, x, \Delta t) \) can be obtained after tracking the computational particles along the characteristic line \( dx/dt = c \) as same as the traditional SP-BGK method. Additionally, the PDF \( f^* (c, x, \Delta t) \) after the particle motion step needs to be reconstructed from Eq. (9a).

For the collision step as shown in Eq. (5b), using the initial PDF generated by the particle motion step \( f^* (c, x, \Delta t) \), the integration solution is applied as same as the traditional SP-BGK method, that is,
\[ f(c, x, \Delta t) = f^* (c, x, \Delta t) e^{-\Delta t/c} + \left(1 - e^{-\Delta t/c}\right) \int_0^{\Delta t} \frac{e^{\epsilon t}}{e^{(c\epsilon/c) - 1}} f_i (c, x, t) dt. \]

It should be noted that if the time step is larger than the mean collision time, the target distribution function \( f_i (c, x, t) \) is no longer reasonable to be assumed constant as in the SP-BGK method, so a particle velocity resampling should be exactly implemented based on Eq. (11). Finally, we can construct \( f^* (c, x, \Delta t) \) using Eq. (9b) and consider it as the initial PDF for the next time step. The procedure described above starting from Eq. (8) is repeated until the simulation is finished, and the detailed algorithm can be found in reference [21].

3. An efficient algorithm of the USP-BGK method

Compared to the traditional SP-BGK method, three more operations need to be implemented in the USP-BGK method. First, according to Eq. (9), the auxiliary PDFs \( \tilde{f} \) and \( f \) should be constructed before and after particle motion; second, according to Eq. (11), an exact integral term of PDF needs to be sampled; third, to be consistent
with the second-order of accuracy in time, the spatial reconstruction based on the particle location should also be implemented. In the previous paper [21], the auxiliary PDFs are constructed by adding virtual particles and a new time sampling method is applied to deal with the integral term. Besides, linear interpolation is used to reconstruct the macroscopic quantities of calculated particles with second-order accuracy in space. The aforementioned operations would inevitably increase the complexity of computation. To make the USP-BGK method as simple as the other particle methods such as DSMC, an efficient algorithm improving temporal evolution and spatial reconstruction is proposed in the present paper.

3.1 Temporal evolution

To avoid employing virtual particles, one can directly update the simulation based on the auxiliary PDFs themselves as shown in the particle motion step Eq. (10). Therefore, only the collision step [Eq. (11)] needs to be modified. For this purpose, the governing equation of the collision step, i.e. Eq. (5b), is modified as

\[
\frac{\partial f}{\partial t} = \frac{1}{\varepsilon} (f_v - f),
\]

where the proposed target distribution \( f_v \) is assumed as

\[
f_v = f_m \left[ 1 + \psi_1 \frac{\sigma_q}{2 \rho T^2} \left( \frac{8}{\pi} \right)^2 C_m C \psi_2 \frac{2 C_q q}{5 \rho T^2} \Pr \left( \frac{8}{\pi} \right) \left( \frac{4 C^2}{\pi T} - \frac{5}{2} \right) \right],
\]

where \( \psi_1 \) and \( \psi_2 \) are two undetermined coefficients. Using the initial PDF \( \tilde{f}^*(c; x, \Delta t) \) obtained from Eq. (10), the numerical solution of Eq. (12) can be written as,

\[
\tilde{f}(c; x, \Delta t) = e^{-\beta t \Delta t} \tilde{f}^*(c; x, \Delta t) + \left( 1 - e^{-\beta t \Delta t} \right) f_v^*(c; x, \Delta t).
\]

Letting the right-hand side of Eq. (14) equals to \( \tilde{f}(c; x, \Delta t) \) that obtained from Eq. (11), then \( \psi_1 \) and \( \psi_2 \) can be determined. Note that Eqs. (10) and (14) have the same form as the solutions of the particle motion and collision steps of the traditional SP-BGK method [22] except for the different target distribution. In this way, virtual particles are not needed for simulation.
Next, we exactly derive Eq. (11) in the USP-BGK method. In the present algorithm, the Shakhov BGK model is employed to correct the Pr number, i.e. the target distribution reads

$$f_t = f_i = f_{M} \left[ 1 + (1 - \text{Pr}) \frac{2C_1 q_i}{5 \rho T} \left( \frac{8}{\pi} \right) \left( \frac{4C_2^2}{\pi T} - \frac{5}{2} \right) \right].$$  (15)

Substituting it into Eq. (11), we have

$$\tilde{f}(c,x,\Delta t) = e^{-\Delta t \nu} \tilde{f}(c,x,\Delta t) + (1 - e^{-\Delta t \nu}) f_M \left[ \int_{-\infty}^{\infty} e^{\rho \nu} \left( e^{\rho \nu} - 1 \right) c \frac{2C_1 q_i}{5 \rho T} \left( \frac{8}{\pi} \right) \left( \frac{4C_2^2}{\pi T} - \frac{5}{2} \right) \right] \left[ \frac{2C_1 q_i}{5 \rho T} \left( \frac{8}{\pi} \right) \left( \frac{4C_2^2}{\pi T} - \frac{5}{2} \right) \right].$$  (16)

Multiplying $mC_j$ and $mC_j^2/2$ on both sides of Eq. (5b) and taking ensemble average, the moment equation of the shear stress and heat flux are obtained as

$$\frac{\partial \sigma_{ij}}{\partial t} = -1 \frac{\partial q}{\partial x_j} + \frac{P_c}{\varepsilon} \sigma_{ij}^*, \quad (17a)$$
$$\frac{\partial q_j}{\partial t} = -\text{Pr} \frac{\partial q_j}{\partial x_j} + \frac{P_c}{\varepsilon} q_j^*. \quad (17b)$$

Hence, the solution of the shear stress and heat flux at time $t$ are

$$\sigma_{ij}(t) = e^{-\nu \Delta t} \sigma_{ij}^* + (1 - e^{-\nu \Delta t}) P_c \sigma_{ij}^*. \quad (18a)$$
$$q_j(t) = e^{-\nu \Delta t} q_j^* + (1 - e^{-\nu \Delta t}) P_c q_j^*. \quad (18b)$$

Substituting it into the right-hand side of Eq. (16), then $\tilde{f}(c,x,\Delta t)$ is obtained

$$\tilde{f}(c,x,\Delta t) = e^{-\nu \Delta t} \tilde{f}(c,x,\Delta t) + (1 - e^{-\nu \Delta t}) f_M \left[ \int_{-\infty}^{\infty} e^{\rho \nu} \left( e^{\rho \nu} - 1 \right) c \frac{2C_1 q_i}{5 \rho T} \left( \frac{8}{\pi} \right) \left( \frac{4C_2^2}{\pi T} - \frac{5}{2} \right) \right] \left[ \frac{2C_1 q_i}{5 \rho T} \left( \frac{8}{\pi} \right) \left( \frac{4C_2^2}{\pi T} - \frac{5}{2} \right) \right].$$  (19)

Compared Eq. (14) with Eq. (19), the undetermined coefficients are calculated as

$$\psi_1 = P_c \left[ \frac{2e^{-\nu \Delta t} + (1 - e^{-\nu \Delta t}) P_c}{(1 - e^{-\nu \Delta t})} \right] \frac{\Delta t}{2} P_c \varepsilon \quad \text{and} \quad (20a)$$
\[
\psi'_{2} = \left[ (1 - Pr) e^{-\frac{Pr \Delta t}{\bar{c}}} - e^{-\frac{\bar{c}}{\Delta t}} + Pr \right] \frac{Pr (1 - e^{-\frac{\bar{c}}{\Delta t}})}{2} \Delta t \frac{Pr}{\epsilon}.
\]

(20b)

From Eq. (14), we can obtain \( \tilde{f}(c; x, \Delta t) \) after the collision step, and then it is directly applied to particle motions in the next time step. Note that this technique has been first introduced in the USPBGK-DSMC hybrid method [22]. In the hybrid method, the USP-BGK method is only applied to the continuum regime, and the rarefied regime is solved by DSMC. In this work, with the multi-scale parameter \( P_c \), the present algorithm is used in the whole flow regimes.

As shown in Eq. (7), \( P_c \) is assumed as a function of the gradient-length based local Knudsen number, which is calculated from the gradients of macro quantities, such as density, velocity and temperature. As gradients cannot be directly obtained in the particle methods, here we choose \( P_c = e^{-\alpha \Delta t / \Delta t} \) instead and set \( \alpha = 0.1 \). Note that \( \varepsilon / \Delta t \) is also a good estimator for the rarefaction as presented in ref. [22], and importantly it can be calculated from the PDF of local computational particles.

3.2 Spatial reconstruction

To reach a second-order accuracy, besides the temporal evolution, it also requires the same order of accuracy in space. In the particle motion step, the particle tracking is exactly solved; however, in the collision step, to reconstruct the target distribution at the location of the simulated particle, the mean velocity and temperature with second-order accuracy need to be interpolated based on the flow field. In CFD, there are a lot of methods to obtain second-order interpolation, such as the linear interpolation used in the previous paper [21]. However, calculating interpolation would bring extra complexity to the program code. Moreover, its statistical noise would introduce additional numerical dissipation and instability. On the other hand, in most stochastic particle methods such as DSMC, they only need to deal with the local macro variables. Therefore, the interpolation module is usually not required in DSMC codes. In order to
transplant the USP-BGK method to the existing DSMC software easily, an interpolation technique based on particle tracking is proposed as follows.

Mean quantities of the computational particle, such as the mean velocity \( u_x(x_p,t) \) and temperature \( T_x(x_p,t) \), equal to the macro velocity \( U(x_p,t) \) and temperature \( T(x_p,t) \) of the flow field at the particle location \( x_p \) and time \( t \), i.e. \( u_x(x_p,t) = U(x_p,t) \) and \( T_x(x_p,t) = T(x_p,t) \). We assume that the macro variables of the flow field at the same location are averaged from surrounding particles, taking macro velocity as an example, it is approximated as

\[
U(x_p,t) = \frac{1}{N_p} \sum_{j=1}^{N_p} U(x_j,t;x_p+\Delta x \in j)K(\Delta x),
\]

where \( U(x_j,t;x_p+\Delta x \in j) \) represents the macro velocity of the cell \( j \), which contains the sampling particle that located at \( x_p+\Delta x \), and \( x_j \) is the cell center. \( K(\Delta x) \) is a symmetric kernel, which represents the spatial distribution of sampling particles. The number of sampling particles is

\[
N_p = \int f K(\Delta x) d\Delta x = \int f K(\Delta x) d\Delta x = \int f K(\Delta x) d\Delta x = \sum_{j=1}^{N_p} K(\Delta x).
\]

Note that the auxiliary PDFs do not change the averaging results. In Eq. (21), we approximate the mean velocity of the sampling particle at \( x_p+\Delta x \) with the macro velocity of the cell. As shown in proposition 3.1, the estimator of \( U(x_p,t) \) with such simplification can also obtain second-order accuracy.

**Proposition 3.1** With a symmetric kernel \( K(\Delta x) \), the macro velocity and its derivation obtained from Eq. (21) have second-order accuracy.

**Proof.** If replaced \( U(x_j,t;x_p+\Delta x \in j) \) by the exact mean velocity of sampling particle at \( x_p+\Delta x \), then Eq. (21) is rewritten as

\[
U(x_p,t) = \frac{1}{N_p} \sum_{j=1}^{N_p} u_x(x_p+\Delta x,t)K(\Delta x).
\]
Using Taylor expansion, Eq. (23) is expanded as

$$U(x_p, t) = \sum_{j=1}^{N_p} \left[ u_j(x_{p,j}, t) + \frac{\partial^2 u_j(x_{p,j}, t)}{\partial x^2} \Delta x^2 + O(\Delta x^4) \right] K(\Delta x) \frac{\partial}{\partial x} \left[ \frac{\partial U(x_{p,j}, t)}{\partial x} \Delta x + O(\Delta x^2) \right] \right] K(\Delta x)$$  \tag{24}

If choosing $K(\Delta x)$ as a symmetric function, it is easily found that the first-order term vanishes and the macro velocity and its derivation based on Eq. (23) have second-order accuracy.

Next, combining Eqs. (21) and (23), the error between $U(x_p, t)$ and $U(x_p, t)$ is calculated as

$$Error(U \cdot U') = \sum_{j=1}^{N_p} \left[ \frac{U(x_{p,j}, t) - u_j(x_{p,j}, \Delta x)}{N_p} \right] K(\Delta x)$$  \tag{25}

Taking Taylor expansion around $x_p$ again, we obtain

$$Error(U \cdot U') = \sum_{j=1}^{N_p} \left[ \frac{\partial U(x_{p,j}, t)}{\partial x} \Delta x - a_2 \Delta x^2 + O(\Delta x^3) \right] K(\Delta x)$$  \tag{26}

Since $x_j$ is determined by $\Delta x$ and $x_p$, it can be expanded as

$$x_j = x_p + a_2 \Delta x^2 + O(\Delta x^3)$$

Substituting it into Eq. (26), it is obtained

$$Error(U \cdot U') = \sum_{j=1}^{N_p} \left[ \frac{\partial U(x_{p,j}, t)}{\partial x} \Delta x - a_2 \Delta x^2 + O(\Delta x^3) \right] K(\Delta x)$$  \tag{27}

where the first-order term of $\Delta x$ vanishes due to the symmetric kernel. Therefore, according to Eq. (24) and (27), the estimator $U(x_p, t)$ introduced in Eq. (21) also satisfies the second-order accuracy in space, if a symmetric kernel is employed.

In simulations, it is not necessary to take the average for $N_p$ particles as Eq. (21) at every time step. Instead, only one sampling particle is required, i.e. a random distance $\Delta x$ can be first sampled based on the kernel function, then the mean velocity of the computational particle is taken as the macro velocity of the cell where the sampling particle is located. Therefore, we can simply assume the mean velocity of the simulated
particle as
\[ u(x_p, t) = U(x_j, t; x_p + \Delta x \in j). \] (28)

Similarly, the temperature of the computational particle is taken as
\[ T(x_p, t) = T(x_j, t; x_p + \Delta x \in j). \] (29)

Applying Eqs. (28) and (29), only the macro variables of the cell are required when calculating the collision step.

Two symmetric kernels are employed and tested in the present paper, one is the uniform kernel, i.e.
\[ K_{linear}(\Delta x) = \begin{cases} 
1 & \Delta x_i \in [-\Delta h/2, \Delta h/2] \\
0 & \text{otherwise}
\end{cases}, \] (30)

where \( \Delta h \) is the cell size. Another one is the Gaussian kernel, i.e.
\[ K_{gauss}(\Delta x) = \left( \frac{1}{2\pi\sigma} \right)^{3/2} \exp\left( -\frac{\Delta x^2}{2\sigma^2} \right), \] (31)

where \( \sigma = (\Delta h/2)^2 \). Note that it is free to use any other symmetric kernels.

3.3 Implementations of the efficient algorithm of the USP-BGK method

According to the algorithm introduced in sections 3.1 and 3.2, its implementations are outlined in Table 1.

| Table 1. Outline of the efficient algorithm of the USP-BGK method |
|---------------------------------------------------------------|
| **1. Initialization** | Introduce initial computational particles in the computational domain. Their velocities are sampled from the initial auxiliary PDF \( \tilde{f}(c; x, 0) \). |
| **2. Streaming** | Move the computational particles with their velocities and apply boundary conditions to obtain \( \tilde{f}^*(c; x, \Delta t) \). |
| **3. Collision** | \( (1 - e^{-\Delta t/c}) \) part of particles are randomly selected from the cell to assign new velocities, which are sampled from the PDF \( f_c \); the velocities of the remaining part of particles are unchanged. |
\( f_v \) is calculated based on Eqs. (13) and (20). Their mean
velocity and temperature are obtained based on particle tracking
interpolation as shown in Eqs. (28) and (29), respectively. \( \sigma_v^i \)
and \( q_v^i \) are obtained according to Appendix A.

After the collision step, the PDF of the computational particles
is equal to \( \tilde{f}(c; x, \Delta t) \) and prepared for the next time step.

4. Sampling
Sample the macroscopic quantities (also see Appendix A).

In addition, after resampling particle velocity in the collision step, the momentum
and energy conservation should be ensured in every cell. Therefore, the particle
velocities need to be modified as,

\[
e = \left( e^i - \frac{\sum_{i=1}^{N_c} \epsilon_i}{N_c} \right) \frac{RT (N_c - 1)}{\left( \sum_{i=1}^{N_c} \epsilon_i \right)} + U,
\]

(32)

where \( e^i \) and \( e \) represent the velocities before and after modification, respectively. 
\( N_c \) is the number of particles in the cell.

4. Numerical simulations

4.1 Homogeneous relaxation

The relaxation process in the homogeneous flow is first investigated to validate the time
scheme in the collision step, i.e. Eq. (14). The initial velocity PDF is described by the
13 moments Grad’s distribution function, i.e.

\[
f_{\text{grad}} = \left[ 1 + \frac{\sigma_v}{2 \rho T^2} \left( \frac{8}{\pi} \right)^2 C_v C_{p} + \frac{2 q C_v}{5 \rho T^2} \left( \frac{8}{\pi} \right)^2 \left( \frac{4 C_v^2}{\pi T} - \frac{5}{2} \right) \right] f_m,
\]

(33)

where the number density is set to be \( n_0 = 1.885 \times 10^{20} m^{-3} \), the initial velocity is zero and
temperature is \( T_0 = 273K \). The initial shear stress and heat flux are \( 0.1 p_0 \) and
\( 0.1 p_0 \sqrt{k_B T_0 / 2m} \), respectively, and \( p_0 = n_0 k_B T_0 \). Argon gas is considered and \( P_v \) is set to
be zero for the homogeneous case. Four different time-step sizes are calculated and compared, i.e. \( \Delta t \in \{0.1 \tau_c, 0.25 \tau_c, 2.0 \tau_c, 4.0 \tau_c\} \), and \( \tau_c \) is the mean collision time. Figure 1a shows the relaxation of shear stress and heat flux. All of the results are consistent with each other and independent of the time step. Figure 1b gives the evolution of the temperature. We note that energy conservation is also well ensured for a wide range of time step size.

![Figure 1](image)

**Figure 1.** (a) relaxation of shear stress and heat flux; (b) temperature evolution in the homogeneous flow with four different time step size \( \Delta t \in \{0.1 \tau_c, 0.25 \tau_c, 2.0 \tau_c, 4.0 \tau_c\} \).

## 4.2 Sod tube

The Sod’s 1D shock tube problem is a typical multiscale gas flow, and here a case selected from ref. [27] is simulated. The length of the tube is 1 m, and initially there exists a discontinuity in the density at \( x = 0.5 \) m. The initial density on the left and right-hand sides of the discontinuities are \( 10^{-4} \text{ kg/m}^3 \) and \( 0.125 \times 10^{-4} \text{ kg/m}^3 \), respectively. The macro velocity of the gas flow is zero and the temperature is 273K at the beginning. Argon gas is considered, and the viscosity exponent \( \omega \) is 0.81, i.e. \( \mu = \mu_0 \left( \frac{T}{T_{ref}} \right)^\omega \), \( \mu_0 = 2.117 \times 10^{-5} \text{ Pa s} \) and \( T_{ref} = 273K \). In this simulation, 60 uniform cells were employed, and the time step size was four times larger than the mean collision time of the left-hand side tube. The efficient USP-BGK method computes up to the final time.
\( t_{\text{final}} = 6.8 \times 10^{-4} \text{s} \), and two kernel functions, i.e. uniform and Gaussian, are tested. Figure 2 shows the temperature and density distribution at the final time. The results of the two kernel functions agree with each other and both are in good agreement with DSMC. Since the varied density, the ratio between the time step and the local mean collision time change from 4.0 to 0.5 through the tube, i.e. \( \Delta t \in [0.5\tau_c, 4.0\tau_c] \). Therefore, the results of Fig. 2 also indicates that the efficient USP-BGK method with both uniform and Gaussian kernels can well capture the multi-scale gas flow.

\[
\begin{align*}
\text{Figure 2:} & \quad (\text{Color online}) \text{ Sod tube case. (a) temperature and (b) density at the final time } t_{\text{final}} = 6.8 \times 10^{-4} \text{s}. \text{ The solid lines are results of DSMC obtained by S. Tiwari [27] and the symbols refer to the efficient USP-BGK results.}
\end{align*}
\]

4.3 Taylor-Green vortex flow

The Taylor-Green vortex flow [28] is widely used to investigate the order of accuracy. For a 2D and low Mach number flow, the analytic solutions of the Taylor-Green vortex flow can be obtained from the Navier–Stokes equation, i.e.

\[
U_x(x, y, t) = -U_0 \cos(k_x x) \sin(k_y y) e^{-\frac{x^2}{\mu t}} ,
\]

\[
U_y(x, y, t) = \frac{k_x}{k_y} U_0 \cos(k_x x) \sin(k_y y) e^{-\frac{x^2}{\mu t}} , \quad \text{and}
\]

\[
p(x, y, t) = p_0 - \frac{1}{4} \rho_0 U_0^2 \left[ \cos(2k_x x) + \left( \frac{k_x}{k_y} \right)^2 \cos(2k_y y) \right] e^{-\frac{x^2}{\mu t}} ,
\]
where $U_0$ and $p_0$ are the reference velocity and pressure, respectively. $k_x = 2\pi / L_x$ and $k_y = 2\pi / L_y$ represent the wavenumbers in x and y directions, and $k = \sqrt{k_x^2 + k_y^2}$. $L_x$ and $L_y$ are the length of the two-dimensional computational domain, $L_x = L_y = 1.0 \text{ m}$. In the current simulation, we set the Mach number $Ma = U_0 / \sqrt{\gamma RT_0} = 0.1$, and the reference temperature $T_0 = 273K$. The Reynolds number $Re = \rho_0 U_0 L_x / \mu_0 = 100$, and the reference viscosity is set as same as that in the Sod tube case. The initial velocity of the particles is sampled from the PDF of first-order Chapman-Enskog expansion, in which the macro quantities and their derivatives are computed by the analytical solutions in Eqs. (34) and (35) at $t = 0$. Besides, the initial density is assumed to be uniform in the computational domain and equals to $\rho_0$. Then the initial temperature is calculated from Eq. (36).

The Taylor-Green vortex flow is simulated up to the final time $t = \ln(2) / (k^2 \mu / \rho)$.

Uniform meshes in two dimensions are employed, and the number of computational cells changes from $20 \times 20$ to $50 \times 50$. The time step is determined by the CFL number, which is 0.4 in all cases. Fig. 3 presents the $L_2$-norm of errors of $U_x$ depended on the cell size $\Delta h$, and $U^s_x$ is the accurate solution obtained in Eq. (34). We note that both the uniform and Gaussian kernels can obtain second-order accuracy, and the numerical dissipation of the uniform kernel is smaller than the Gaussian one.
The uniform and Gaussian kernel functions are employed.

4.4 Two-dimensional Riemann problem

For the compressive gas flow, one of the two-dimensional Riemann problems is studied [29]. The computational domain is set as \([0, 1] \times [0, 1]\) \((m)\). Constant initial data is taken in each quadrant, i.e.

\[
(\rho, U, V, p) = \begin{cases} 
(0.5313, 0.0, 0.0, 0.4) & x \in [0.5, 1], \ y \in [0.5, 1] \\
(1.0, 0.7276, 0.0, 1.0) & x \in [0.0, 0.5], \ y \in [0.5, 1] \\
(0.8, 0.0, 0.0, 1.0) & x \in [0.0, 0.5), \ y \in [0.0, 0.5) \\
(1.0, 0.0, 0.7276, 1.0) & x \in [0.5, 1], \ y \in [0.0, 0.5) 
\end{cases}
\]

where \(U\) and \(V\) normalized by \(\sqrt{RT_0}\) are the macro velocity in \(x\) and \(y\) direction, and \(T_0 = 273K\). The density and pressure are normalized by \(\rho_0 = 1.78kg/m^3\) and \(p_0 = \rho_0RT_0\), respectively, and Argon gas is applied. A \(200 \times 200\) uniform mesh is employed, and the CFL number is set to be 0.4. The viscosity is also set as same as that in the Sod tube case. Figure 4 shows the density contours at \(t = 0.2/\sqrt{RT_0}\). It is noted that the uniform and Gaussian kernels obtain a consistent result and both can capture the shock wave properly.
Figure 4: Density distribution of the 2D Riemann problem using the efficient USP-B GK method with (a) Gaussian and (b) uniform kernel functions.

5. Conclusion

The USP-BGK method can calculate the multi-scale gas flow much more efficient than the traditional stochastic particle methods. To simplify the implementation of the USP-BGK method, a new temporal evolution and spatial reconstruction scheme was presented in the present work. Four typical numerical cases, such as the homogeneous and multi-scale sod tube flows, the weak and strong compressive flows, have been used to validate this efficient algorithm. Without additional virtual particles and spatial interpolation, the efficient algorithm of USP-BGK implements as same as DSMC except for the collision term, which resampling a target distribution like the traditional BGK particle method [19]. Therefore, a USP-BGK programme can be easily accomplished based on any DSMC codes by replacing the collision module only. This algorithm can also be implemented in the hybrid USPB GK-DSMC method and would reduce the complexity of the computing programme significantly.

Appendix A Calculation of macroscopic quantities from the auxiliary PDFs

Since the collision operator conserves mass, momentum, and energy, the conserved variables can be calculated from the auxiliary PDFs directly, they are

\[ \rho = \int m f d c = \int m f^d d c = \int m f^d d c , \]

(A1)

\[ \rho U_i = \int m c_i f d c = \int m c_i f^d d c = \int m c_i f^d d c \quad \text{and} \]

(A2)

\[ \rho e = \frac{3}{2} \rho RT = \int \frac{1}{2} m C_i^2 f d c = \int \frac{1}{2} m C_i^2 f^d d c = \int \frac{1}{2} m C_i^2 f^d d c . \]

(A3)

Multiplying Eq. (9) with \( m C_i C_j \) and \( m C_i^2 C_j / 2 \) and taking integral over the velocity space, the shear stress and heat flux can be obtained as
\[
\sigma_{ij} = \int mC_{i,j}^2 \tilde{f} \, dc = \frac{2}{2 - P_{\Delta t} / \epsilon} \int mC_{i,j}^2 \tilde{f} \, dc = \frac{2}{2 + P_{\Delta t} / \epsilon} \quad \text{and} \quad \text{(A4)}
\]

\[
q_i = \frac{1}{2} \int mC^2 \tilde{f} \, dc = \frac{1}{2 - P_{\Delta t} \Delta t / \epsilon} \int mC_i^2 \tilde{f} \, dc = \frac{1}{2 + P_{\Delta t} \Delta t / \epsilon} \quad \text{(A5)}
\]

In a computational cell with volume \( V_c \) and \( N_c \) particles, the above macro quantities are averaged over particles using Eqs. (A1)-(A5), i.e. in detail

**Density:** \( \rho = mN_c / V_c \), \quad \text{(A6)}

**Macro velocity:** \( U_i = \frac{\sum_{i=1}^{N_c} c_{i,k}}{N_c} \), \quad \text{(A7)}

**Temperature:** \( T = \frac{\sum_{i=1}^{N_c} (c_{i,k} - U_i)^2}{R(N_c - 1)} \), \quad \text{(A8)}

**Shear stress (from} \( \tilde{f} \):** \( \sigma_{ij} = \frac{N_c}{N_c - 1} \frac{2}{2 + P_{\Delta t} / \epsilon} \sum_{i=1}^{N_c} m(c_{i,k} - U_i)(c_{i,k} - U_j) / V_c \), \quad \text{(A9)}

**Heat flux (from} \( \tilde{f} \):** \( q_i = \frac{N_c^2}{(N_c - 1)(N_c - 2)} \frac{1}{2 + P_{\Delta t} \Delta t / \epsilon} \sum_{i=1}^{N_c} m(c_{i,k} - U_i)(c_{i,k} - U_j) / V_c \) \quad \text{(A10)}

The factor \( 1/(N_c - 1) \) in the temperature and shear stress occurs to produce unbiasedness of \( T \) and \( \sigma_{ij} \), respectively. Similarly, the unbiased factor in the heat flux is \( N_c / (N_c - 1)(N_c - 2) \) \[19\].
