We investigate the scaling properties of the Barkhausen effect, recording the noise in several soft ferromagnetic materials: polycrystals with different grain sizes and amorphous alloys. We measure the Barkhausen avalanche distributions and determine the scaling exponents. In the limit of vanishing external field rate, we can group the samples in two distinct classes, characterized by exponents $\tau = 1.50 \pm 0.05$ or $\tau = 1.27 \pm 0.03$, for the avalanche size distributions. We interpret these results in terms of the depinning transition of domain walls and obtain an expression relating the cutoff of the distributions to the demagnetizing factor which is in quantitative agreement with experiments.

The Barkhausen noise is an indirect measure of complex microscopic magnetization processes and is commonly employed as a tool to investigate ferromagnetic materials [1]. In recent years, the interest for this phenomenon has grown considerably due to the connections with disordered systems and non-equilibrium critical phenomena.

Experiments have shown that the histogram of Barkhausen jump (avalanche) sizes follows a power law distribution $p \sim s^{-\tau}$, suggesting the presence of an underlying critical point $\tau$. This hypothesis implies that the statistical properties of the noise should be described by universal scaling laws, with critical exponents that are independent of the material microstructure, at least for some class of materials. However, the exact nature of the critical behavior is still debated. Several authors have analyzed the dynamics of flexible domain walls in random media relating the Barkhausen exponents to the scaling expected at the depinning transition. Other theoretical explanations involve a critical point tuned by the disorder in the the framework of disordered spin models.

The experiments reported in the literature can hardly resolve the theoretical issues since the measured exponents span a relatively wide range [2,5,11] and it is difficult to confirm whether universality holds. In particular, there has been no extensive and systematic measurement of critical exponents in different materials with homogeneous and controlled experimental conditions and reliable statistics. For example, experimental evidence of universality has recently been reported for acoustic emission avalanches recorded during martensitic transformations, by analyzing in detail the behavior of several alloys with different compositions [12].

The precise dependence of the Barkhausen characteristic sizes on experimentally tunable parameters is still a debated question [13,14,15] and a complete agreement between theory, simulations and experiments is still lacking. Understanding this point is crucial in order to link the material microstructure to the noise properties, or conversely to use the noise to obtain information on the structure of the material. In the past, this problem, which has important technological relevance, has been mainly addressed using phenomenological models [14,15] where the material properties (i.e. grain size [14], internal stresses [15]) are accounted for by effective fitting parameters. The main limit of this approach is that there is no systematic way to implement the program, without a precise understanding of the microscopic dynamics.

In this letter, we report experimental data for a large set of materials suggesting the existence of two distinct universality classes and show that the results are in quantitative agreement with the theory of domain wall depinning transition. We perform Barkhausen noise measurements in six different ferromagnetic materials under similar experimental conditions, averaging the distributions over a large number ($\sim 10^5 - 10^6$) of events, carefully testing the effect of the magnetic field rate on the exponents. The cutoff of the distributions is tuned by the demagnetizing factor and defines two new critical exponents, which we measure for two materials belonging to the different classes. Using scaling arguments, we predict values for these exponents that are in good agreement with experiments.

We record the Barkhausen noise using standard inductive methods, described in details in Refs. [3,5]. A long solenoid provides an homogeneous low frequency triangular driving field, while a secondary pickup around the sample cross section gets the induced flux. The solenoid is 60 cm long, with a value of 1450 turns/meter, ensuring an homogeneous field up to 55 cm long samples with peak amplitude of about 150 A/m. The pickup is made of 50 isolated copper turns, wounded within 1 mm. Such a small width is required to avoid spurious effects due to demagnetizing fields. All the measurements are performed only in the central part of the hysteresis loop around the coercive field, where domain wall motion is the relevant magnetization mechanism. We take special care to reduce excess external noise during the measurements of avalanches distributions, as the evaluation of critical exponents is strongly affected by spurious noise. In this respect, the most appropriate cutoff frequency of the low pass pre-amplifier filter is chosen in the 3-20 kHz range, roughly half of the sampling frequency, as usual in noise...
measurements.

The analysis of Barkhausen avalanche distribution is performed following the procedure discussed in Ref. [3]. We impose a reference level for $v_r$ for the signal $v(t)$, chosen above the background noise. The duration $T$ of the Barkhausen avalanches is defined as the interval within two successive intersections of the signal with the $v = v_r$ line. The avalanche size $s$ is calculated as the integral of the signal between the same points. We observe that the avalanche distributions follow a power law

$$P(s) = s^{-\gamma} f(s/s_0), \quad P(T) = T^{-\alpha} g(T/T_0), \quad (1)$$

where $s_0$ and $T_0$ indicate the position of the cutoff to the power law behavior. The critical exponents result to be independent of the reference level for a reasonable range of $v_r$. [3]

We employ several different soft magnetic materials, both polycrystalline and amorphous: an Fe-Si 7.8 wt.\% strip (30 cm × 0.5 cm × 60 μm) produced by plan flow casting, annealed several times around 950°C to obtain grains of average dimension of 25 μm; two strips of Fe-Si 6.5 wt.% (30 cm × 0.5 cm × 45 μm), one annealed for 2h at 1200°C, with grains of 160 μm, and the other annealed for 2h at 1050°C, with grains of 35 μm. [4]. The amorphous samples have composition of the type Fe$_x$Co$_{88-x}$B$_{15}$ and we employ Fe$_{21}$Co$_{64}$B$_{15}$ as cast (20 cm × 1 cm × 22 μm), Fe$_{64}$Co$_{21}$B$_{15}$ as cast (28 cm × 1 cm × 23 μm). With these highly magnetostriuctive alloys ($\lambda_\alpha \sim 30 – 50 \times 10^{-6}$) a tensile stress of $\sigma \sim 100$ MPa is applied during the measurement. The applied stress is found to enhance the signal-noise ratio, reducing biases in the distributions, but does not change the exponents [7]. A partially crystallized Fe$_{64}$Co$_{21}$B$_{15}$ (22 cm × 1 cm × 23 μm) is also employed, with annealing for 30 min at 350°C and then for 4h at 300°C under an applied tensile stress of 500 MPa. This induces the formation of α-Fe crystals of about 50 nm, with a crystal fraction of $\sim 5\%$. [8]

In Fig. 1a we show the avalanche size distribution, obtained for the smallest available magnetic field rates ($f = 3-5$ mHz). We clearly see that the data can be grouped in two universality classes with $\tau = 1.50 \pm 0.05$ and $\tau = 1.27 \pm 0.03$. The first class includes all the Si-Fe polycrystals and the partially crystallized amorphous alloy, while the amorphous alloys under stress belong to the second class. For the materials in the first class, we observed a linear decrease of the exponents on the frequency $f$ of the external magnetic field, in agreement with earlier findings [9]. The material in the second class do not show any noticeable dependence of the exponents on the field rate. We note that $\tau \approx 1.3$, independent of the frequency, was previously measured in Perminvar [10].

Next, we measure the distribution of avalanche durations (see Fig. 1b) and find $\gamma = 2.0 \pm 0.2$ and $\alpha = 1.5 \pm 0.1$ for the two classes, with a quite large error bar due to the limited range of scaling, and the presence of unavoidable excess external noise at low durations. Also in this case, $\alpha$ decreases linearly with $f$ for the materials belonging to the first class.

The scaling of the cutoff of Barkhausen avalanche distributions has been the object of an intense debate in the literature [11,12]. In Ref. [3] the control parameter was identified with the demagnetizing factor $k$. We thus measure the Barkhausen avalanche distributions varying $k$, using samples of different aspect ratios. In particular, we use the same sample and cut it progressively in shorter pieces, recording the noise always in the same region, whose size is limited by the pickup coil width. In this way only $k$ is varied, while stress, internal disorder and system size are kept constant. The demagnetizing factor is estimated as $k = 1/\mu_c - 1/\mu_i$ where $\mu_c$ is the linear permeability around the coercive field and $\mu_i$ is the intrinsic permeability (i.e. in an infinite strip) estimated using a magnetic yoke [13].

We perform the measurements on the Fe-Si 6.5 wt.% 1200°C (with lengths spanning from 28 to 10 cm) and the Fe$_{21}$Co$_{64}$B$_{15}$ (from 27 to 8 cm) under constant tensile stress. In Fig. 2 we report the avalanche size distribution for different $k$ for Fe$_{21}$Co$_{64}$B$_{15}$ in order to show the increase of the cutoff. Data collapse analysis yields $s_0 \sim k^{-1/\alpha}$ with $1/\alpha \approx 0.78$ (see the inset of Fig. 2). Similarly the duration distribution cutoff scales as $s_0 \sim k^{-\Delta}$ with $\Delta \approx 0.4$. In the case of Fe-Si, the analysis is complicated by the frequency dependence of the exponents, therefore we fit the cutoff for different values of $f$ and extrapolate the results for $f \to 0$. The results for $s_0$ and $T_0$ for both materials are reported in Fig. 3 and Table I.

To interpret the experimental results we use the model of domain wall depinning discussed in Ref. [11,12]. A single 180° domain wall is described by its position $h(\vec{r})$, dividing two regions of opposite magnetization directed along the $x$ axis. The total energy for a given configuration is the sum of different contributions due to magnetostatic, ferromagnetic and magneto-crystalline interactions, and gives rise to the following equation of motion [8]:

$$\Gamma \frac{\partial h(\vec{r}, t)}{\partial t} = 2\mu_0 M_s H - k \int d^2r' h(\vec{r}', t) + \gamma_w \nabla^2 h(\vec{r}, t)$$

$$+ \int d^2r' J(\vec{r} - \vec{r}') (h(\vec{r}') - h(\vec{r})) + \eta(\vec{r}, h),$$

where $\Gamma$ is the viscosity, $M_s$ is the saturation magnetization, $H$ is the applied field, $k$ is the demagnetizing factor, $\gamma_w$ is the surface tension of the wall, $J$ is the kernel due to dipolar interactions given by

$$J(\vec{r} - \vec{r}') = \frac{\mu_0 M_s^2}{2\pi \rho |\vec{r} - \vec{r}'|^3} \left(1 + \frac{3 \rho - x^2}{|\rho - x|^2} \right),$$

and $\eta(\vec{r}, h)$ is a Gaussian uncorrelated random field taking into account all the possible effects of dislocations, residual stress and non-magnetic inclusions.

The critical behavior of Eq. [2] has been understood using renormalization group methods [20,22], which show
that at large length scales the critical exponents take mean-field values $[11]$. This result is due to the linear dependence on the momentum of the interaction kernel (Eq. 2 in Fourier space [24]). In general, if we consider an interface whose interaction kernel in momentum space scales as $J(q) = J_0|q|^\mu$, the upper critical dimension is given by $d_c = 2\mu$ and the values of the exponents depend on $\mu$ (see Table I). In particular, Eq. 2 with $\mu = 1$ and $\alpha = 2$ (i.e. $\mu = 1$), or $\alpha = 1.27$ and $\alpha = 1.5$ if dipolar interactions are neglected (i.e. $\mu = 2$) [1]. Numerical simulations confirm the linear dependence of the exponents on the driving frequency $f$ for $\mu = 1$, and no dependence for $\mu = 2$ [17].

The experimental results are in perfect agreement with the values predicted using Eq. 2 and suggest that the dipolar interactions are stronger than surface tension effects in polycrystals, or whenever small grains are present, while in amorphous alloys under stress the surface tension is much stronger. Magnetostriction can be one of the sources of this effect, since the domain wall surface tension increases with stress anisotropy and stress [19].

The scaling of the cutoff is different for a local demagnetizing field $-kh(x,t)$ [9], which yields $\nu_k = 1/\mu$ [9]. However, a non-local term is more appropriate to describe the demagnetizing field, due to the long-range of magnetostatic interactions [9], as it is confirmed by the agreement between experiments and theory.

In conclusions, our experiments suggest that the Barkhausen effect can be described by universal scaling functions and that materials can be classified in different universality classes. The theory of interface depinning can be used to obtain a quantitative explanation of the experiments, providing a natural framework to understand the properties of soft magnetic materials.
