ABSTRACT

This paper documents the experience improving the performance of a data processing workflow for analysis of the Human Connectome Project’s HCP900 data set. It describes how network and compute bottlenecks were discovered and resolved during the course of a science engagement. A series of computational enhancements to the stock FSL BedpostX workflow are described. These enhancements migrated the workflow from a slow serial execution of computations resulting from Slurm scheduler incompatibilities to eventual execution on GPU resources, going from a 21-day execution on a single CPU core to a 2 hour execution on a GPU. This workflow contributed a vital use-case to the build-out of the campus compute cluster with additional GPUs and resulted in enhancements to network bandwidth. It also shares insights on potential improvements to distribution of scientific software to avoid stagnation in site-specific deployment decisions. The discussion highlights the advantages of open licenses and popular code collaboration sites like GitHub.com in feeding contributions upstream.

KEYWORDS

Slurm batch scheduler, high performance computing, GPU, research support

1 INTRODUCTION

Research support engagements to facilitate use of advanced computing resources are crucial to improve scientific outcomes and ensure efficient use and operation of resources. The UAB Visual Brain Core (now Civitan International Neuroimaging Laboratory (CINL) Brain Core) is a collaboration between neuro-imaging labs and the research computing support group in central IT [6]. It was created to improve the availability of compute and software resources across campus neuro-imaging research groups. Its mission is to help produce high quality, cutting edge research examining the visual brain. To achieve this, the core helps investigators overcome some common barriers to performing high quality vision research, and provides forums to discuss new ideas and research techniques. The core offers weekly office hours to assist researcher access to computing resources.

Campus compute cluster support for high-performance and high-throughput computing is provided by the research computing support group that is part of the central IT organization. The group operates a recently acquired 2800 core compute cluster with six petabytes of GPFS storage and 72 P100 GPUs. This cluster was built over the past three years and represents a commitment to continued investment in computing support for the campus research community [2].

Opportunities for science engagement often occur serendipitously through ordinary use of resources. The engagement described in this paper resulted from efforts by researchers to prepare for participation in a distributed conference series focused on investigations of the brain. The investigation sought to focus on the HCP900 data set released by the Human Connectome Project (HCP) [8, 10].

2 BRAINHACK GLOBAL AT UAB

Brainhack Global is a conference series inspired by the experience of software hackathons [5]. Similar to hackathons in the tech sector, much of the schedule is left open for attendees to work together on projects of their choosing. Brainhacks are not “coding sprints” or exclusive to programmers, but rather are open to brain scientists.
from all backgrounds. Part of the goal is to get people with different backgrounds working together to understand the brain. Brainhack seeks to convene a global community of researchers across disciplines from across the globe to work on innovative projects related to neuroscience. Each site sponsors a local Brainhack event and shares its activities with the global community. UAB was a participating site in the Brainhack Global 2017 event held March 2-5, 2017 [17].

As part of this event one of the participating researchers set out to prepare the HCP900 dataset for analysis “in a few days” on the campus 2300-core compute cluster. The HPC900 is provided by the Human Connectome Project (HCP) which aims to provide an unparalleled compilation of neural data, an interface to graphically navigate this data, and the opportunity to achieve never before realized conclusions about the living human brain. With the help of the HCP, it is possible to imagine navigating the brain in a way that was never before possible: flying through major brain pathways, comparing essential circuits, zooming into a region to explore the cells that comprise it, and the functions that depend on it.

The HCP900 included structural and diffusion data on 727 subjects, aged 22-36, 44% male. The goal was to facilitate use of FSL’s Probtrackx for probabilistic tractography from both central and far-peripheral regions of interest. This required preprocessing the images to provide the data set inputs needed by the Probtrackx [4]. This preprocessing was accomplished with the Bedpostx tool in FSL.

3 SCALING NETWORK BANDWIDTH

The Human Connectome Project makes multi-Terabyte data sets available by way of the Aspera data transfer client which provides high throughput data transfers via managed UDP data flows [1]. The research support team became aware of the download of the HCP900 data set by way of reports from users who were experiencing connectivity issues to cluster VNC sessions and latency issues in their interactive SSH sessions to the cluster login node. After investigating the network layer performance and capturing SSH flows to the login node, we confirmed that the interactive keystroke latencies were directly measurable on the TCP packet flow via a Wireshark plot, see Figure 3.1. The university network team that operates the Intrusion Protection System (IPS) device in front of the cluster identified an on-going UDP transfer as a potential cause. Interrupting the Aspera data transfer resolved all interactive latency issues and confirmed the source of the network contention was the download of the HCP900 data set. Inspecting the Aspera client configuration revealed that the client is set to limit transfers to 1Gbps. It was difficult to understand, however, that these flows would be causing issues on the 10Gbps rated network interface of the cluster login node.

The university network was undergoing improvements and upgrades to bandwidth facilitated by a campus Science DMZ grant [18]. This grant provided equipment for 10Gbps links to shared research resources and motivated additional campus investment across the network [19]. HPC cluster components are connected internally via 10Gbps or better Ethernet links. Further investigation of the campus network path to the cluster revealed that an inter-switch connection from the cluster network fabric to the campus was still running at 1Gbps. This network link was clearly constrained and now explained why the default Aspera configuration was overloading what should have been adequate bandwidth on the cluster login node. The Aspera client was reconfigured to approximately 70% of its default bandwidth to allow the transfer to continue without impacting other users.

4 SCALING COMPUTE THROUGHPUT

The Oxford Centre for Functional MRI of the Brain (FMRIB) produces the FMRIB Software Library (FSL), a library of tools to process FMRI, MRI, and DTI images of the brain [3, 13]. These tools and their associated pipelines are frequently used by imaging groups on campus to process research subject data sets. The FMRIB Diffusion Toolbox (FDT) library provides utilities for processing diffusion weighted MRIs. Bedpostx is a key preprocessing component of this toolbox that generates probabilities of crossing fibers within a voxel [3, 4]. This provides the necessary inputs for modeling nerve fiber pathways in the brain via tractography. This is a computationally intensive process that must analyze each voxel of an MRI. Bedpostx makes it easy for a user to identify a collection of MRIs for processing and takes care of managing the execution details for stepping through each subject MRI and producing the necessary output files.

4.1 Software Tools on the Cluster

Software application modules are provided to users of the campus compute cluster so that they can easily activate applications in their environment. The modules customize their execution path and other environment settings needed to run an application. The software and modules are deployed using Easybuild, a software packaging and deployment suite that simplifies the effort for research support groups to provide software packages across a wide variety of science domains [9]. Easybuild includes packages for building FSL, making it easy to deploy this tool for the campus neuro-imaging community.

A typical neuro-imaging workflow will involve the user activating their FSL module and then running the Bedpostx application...
with a provided input directory of images. In a non-batch scheduling environment, Bedpostx processes each subject MRI serially on a single core. Bedpostx is actually a collection of shell scripts that feeds input to the tool x/fibres. If the script detects a Sun Grid Engine (SGE) batch scheduling environment (by way of the SGE_ROOT environment variable), it will arrange to split each MRI into its constituent slices and submit each slice as a job to the batch scheduler. This will significantly improve the processing time by reducing the total time per subject to the time it takes to process the slice containing the most voxels, given enough cores to run all slices simultaneously. Images in the HCP900 data set contained approximately 145 slices.

### 4.2 Understanding FSL Application Defaults

Research deadlines put pressure on completing data processing steps as quickly as possible. The research team was working to prepare the HCP900 data set for analysis in time for their upcoming Brainhack event. Producing connectivity maps for each subject was desired. With FSL readily available on the cluster, the team set out to pre-process the complete data set. After some preliminary tests, it was observed that Bedpostx only processed one image at a time and was taking an extensive amount of time to complete. Based on prior experience with FSL and the campus batch scheduler, the team produced a job submit script that would submit each subject individually. The jobs were configured to request 6 cores with 14G per-core (84G total per job) in the longest job runtime configuration (6 days and 6 hours). The hope of this resource request was that it would improve the throughput on each job and provide enough time to complete the analysis. Due to the time constraint, 800+ jobs were submitted at once. Due to limitations in the scheduler configuration that allowed one user to consume as many resources are requested, this job configuration quickly overwhelmed the resources available on the cluster. This resulted in all cores on the cluster being consumed by this single workflow. Naturally other users objected to the resource starvation for their own workflows.

This cluster event caused the research support group to engage in the effort. Conversations with the research team led to an understanding of the goals and the existing assumptions about FSL. The support team investigated the team’s job scripts and researched the operational assumptions of FSL and Bedpostx. The most significant finding was that Bedpostx was only programmed to detect SGE environments. As a result of the recent campus compute upgrades and modernization of batch scheduling capabilities, the campus cluster environment had been migrated from the long-standing SGE batch scheduler to the Slurm batch scheduler four months prior. Because of this, Bedpostx failed to detect a batch computing environment. This caused it to analyze each MRI on a single-core. This was counter to the researcher’s prior experience with Bedpostx, wherein it would automatically run efficiently via the (then SGE) batch scheduler. Finally, the resources requested for each job did little to improve performance because only one of six requested cores was actually performing the computation.

### 4.3 Adapting to the Local Environment

After some research on Bedpostx and reading the code, it was clear that Bedpostx acts as a wrapper script for another script fsl_sub, which actually submits brain slices for processing. We also realized, based on reading the code for fsl_sub, that it was designed exclusively for the SGE scheduler. Since the batch computing environment was now using the Slurm scheduler, we needed to modify fsl_sub to recognize our Slurm environment and submit the brain image slices to it in parallel. This modification was facilitated by an existing FSL patch provided by Trinity College Dublin [15].

We created a test copy of FSL software based on the Trinity patch. Development was tracked using the research support teams GitLab environment. Preliminary changes were made to adjust for local partition naming and job request parameters. With batch submission working, a series of test runs were initiated to observe performance. The updated fsl_sub executable was now able to run all the brain image slices in parallel when using Slurm batch scheduling. The performance of each slice was clearly correlated to the number of voxels per-slice which contain actual brain imaging data (as opposed to a non-data mask). The more data in the slice, the more RAM required and the longer the compute time, as seen in Figure 4.1. Given that each slice is processed independently this kind of scaling provides a solid indication that additional slicing of the data can further improve performance.

This analysis allowed the research support group to tune the requested parameters in the fsl_sub to match the data set, maximizing resource efficiency across jobs. The maximum run time of an individual slice was chosen as the default job request time and job dependencies were introduced to allow the MRI pre- and post-processing (slice decomposition and reconstruction) to operate in a dependency workflow. With Slurm support in place, the total time for processing of a single subject was reduced from 21 days to 7 hours when running all the 145 brain image slices in parallel on 145 cores/cpus. Nonetheless, with 800+ images to process from the HCP900 collection, the entire processing time would have still taking around 21 days to process on the campus cluster, even given all available cores (2300 then) to this single workflow.

### 4.4 Maximizing Throughput with GPU Computing

CPUs use chip space for large, fast memory caches to speed execution of serial codes. GPUs use chip space to add 1000’s of cores to speed execution of data-parallel codes. The GPU is especially well-suited to address problems that can be expressed as data-parallel computations - the same instructions are executed on many data elements in parallel. Many applications that process large data sets can use a data-parallel programming model to speed up their computations. The analysis of x/fibres suggested this was very amenable to GPU computing and, indeed, it was discovered that FSL included a version of x/fibres to run on NVIDIA GPUs with a documented 200x acceleration over a single CPU core [12].

The recent campus cluster expansion included four nodes with a K80 GPU to support exploration with GPU computing. In parallel to the Bedpostx customization for Slurm, the research support team tested the xfibres_gpu application provided with FSL using the CUDA Toolkit v7.5.18. The xfibres_gpu code does a simple...
cudaGetDevice() as its only initialization step to get the current GPU device to run its commands.txt [14]. The commands.txt file is automatically generated and lists the application and parameter combination needed to process the data set.

A custom job script was developed to directly submit x/ibre_gpu runs to the K80 GPU nodes. Additional changes to Bedpostx would have been required to detect GPU capabilities within the Slurm environment. It was easier to simply process each MRI as a single job on the GPU. Each job needed 8 GB of RAM. Each subject was now able to complete in slightly over 2 hours (2 hours 8 minutes). These runs were able to match the documented speedup compared to the original single-core processing time of 21 days. ((21 days * 24 hours) / 2 hours 8 minutes = 236x speedup). An additional benefit was that the image processing could now be moved to dedicated nodes freeing the rest of the cluster to serve other users. Unfortunately, due to the large number of subjects in the HCP900 data set and having only four GPU nodes, processing the entire data set still required 21 days.

Figure 4.1: x/ibre run: file size (MB), RAM used (MB), and processing time (seconds) per-slice in a single-subject MRI

5 RESULTS AND OUTCOMES

5.1 Network Enhancements and the Science DMZ

In response to the discovery of the 1Gbps constriction point, the network team prioritized the upgrade of the problematic 1Gbps link to 10Gbps. This result was obtained within a few days of discovery. Since this upgrade, no similar bandwidth competition issues have been reported. Further testing and use of other transfer protocols, however, has shown the next constriction point is the IPS itself. This motivates moving all significant data flows, including Aspera facilitated transfers, to the Science DMZ fabric being constructed for the cluster.

The ability to run network performance tests that follow the path of user data is crucial to determining performance expectations for data transfers. Regular testing helps identify bandwidth availability patterns and can alert when performance falls outside the norm. The PerfSONAR infrastructure that is part of the ESNet Science DMZ initiative provides valuable tooling for these efforts [7, 11]. The campus has built a Science DMZ as part of the NFS grant with two data transfer nodes (DTNs) and a PerfSONAR node, each with 40Gbps connectivity to 100Gbps network that feeds the campus.

Aspera transfers have been tested on this network and max out at slightly above 1Gbps. This suggests any further transfer improvements will depend on improvements to the HCP900 data delivery network. Nonetheless, adding performance testing software to the cluster login nodes, where most transfers still occur, would have revealed the 1Gbps constriction immediately. This configuration has been problematic because cluster login nodes sit on a private network behind a firewall. This configuration complicates network bandwidth tests because some end-to-end tests only advertise the internal network address of the testing node. Installing network performance testing tools on all relevant data endpoints is a priority for the cluster support team. The DTNs are also in the process of being connected directly to cluster storage which will make them available to production data transfers.

5.2 Local Software Forks and Feeding Improvements Upstream

Maintaining local modifications to software suites across releases requires considerable effort. This is complicated by licensing that limits the ability to distribute modifications of the FSL distribution. Licensing choices can be used to shape the nature of the downstream user community. The changes to FSL described in this paper must be maintained locally. While the Trinity patch formed a useful foundation and sped adaption, site-specific changes were still necessary. In mature open-source software, such site changes are often found in configuration files. The upstream provider has little motivation to develop enhancements that don’t serve their local needs, but a vibrant community around an open source software product can enable downstream users to build these features into the software. This type of community is readily facilitated by popular code collaboration sites like GitHub.com. The changes to the FSL submit functionality to support Slurm have been published on GitHub.com [16].

5.3 Expanding Impact of GPU Computing

The potential of GPU computing to significantly increase the throughput of computationally intense work loads and simultaneously reduce the data center footprint makes it an attractive option for investments focused on expanding computing at the campus. The research support group used the Bedpostx workflow as a test case to evaluate its acquisition decisions for compute expansion. Detecting the number of GPU devices on the system can enhance the

with four P100 GPU nodes six months later. This expanded compute
with 4x NVIDIA P100 GPUs. A single P100 GPU was demonstrated
analyzing the HCP Datasets using GPUs Conference’17, July 2017, Washington, DC, USA
This is very useful for multi-GPU systems. Though we could not
just capacity as needed and in a controlled fashion for select work
analysis and provides a mechanism for the operations team to ad-
the type of job /f_looding experienced during the HCP900 Bedpostx
processes to run on each half of the K80 GPU, doubling the per-
subject throughput of a single GPU node as shown in Figure 5.1.
This is very useful for multi-GPU systems. Though we could not
complete the automation of this splitting process before the Brain-
hack event, we were able to manually test and demonstrate this on
our existing NVIDIA K80 nodes and vendor provided test system
with 4x NVIDIA P100 GPUs. A single P100 GPU was demonstrated
as capable of processing a single subject in 30 minutes, suggesting
a four GPU cluster node has the potential to process a single subject
in less than 10 minutes with a four-way split to the MRI image. This
use case contributed to the decision to acquire 18 compute nodes
with four P100 GPU nodes six months later. This expanded compute
fabric has the potential to process the HCP900 dataset discussed
here in less than 24 hours (tested at 40 seconds of compute time on
a single subject across 68 GPUs). While this pre-processing step
is not run often, the significance of moving a big data workfl
from 21 days per subject to less than 1 day for the entire dataset
can change how researchers envision their science and what can
be accomplished.

5.4 Improvements to Batch Scheduling
Several improvements to the Slurm scheduling environment were
implemented in the months following the Brainhack. The improve-
ments focused on introducing multi-factor priority scheduling to
implement a fair share policy for access to resources. The new pol-
icy provides a priority boost to users who have not used the cluster
over the past month. This helps ensure resource availability for
less frequent cluster users. Also quality of service constraints
have been introduced to prevent a single user for consuming more than
an agreed on fraction of cluster compute and memory resources,
currently approximately 15% and 30%, respectively. This prevents
the type of job flooding experienced during the HCP900 Bedpostx
analysis and provides a mechanism for the operations team to ad-
just capacity as needed and in a controlled fashion for select work
loads.

5.5 Learning by Example
The preparatory work that the Bedpostx application does to manage
the staging of data pipelines provides a useful example of workflow
construction and management. The complexity of managing multi-
ple phases of a workflow can be hidden from the end user, providing
them with a simple command-line tool that can hide significant
processing effort via automated job submission. In some respects,
these wrappers can be considered early incarnations of domain-
specific science gateways, hiding complex cluster details behind a
simplified user interface. Exposure to such workflow implemen-
tations helps expose research support teams to opportunities for
improving the local cluster environment for users.

The Bedpostx implementation also demonstrates the utility of
developing multi-job workflows with inter-job dependencies. For
example, the Bedpostx workflow for interacting with batch com-
puting includes a pre-processing step that splits MRI images into
chunks, either by MRI slices for traditional CPU bound jobs or
by groups of slices based on the number of available GPUs. The
next step in the workflow is the actual computation on each chunk.
The workflow concludes with the reassembly of the chunks into a
final data set for following stages. Arranging this workflow as a
sequence of job dependencies allows each stage to request only its
required resources. The pre- and post-processing steps are light-
weight, sequential processes that simply split or reassemble data
files. The computational step they surround can then request the
resources it needs. This tunes resource consumption specific to
each stage of the workflow.

6 CONCLUSION
More than anything, this is a record of the depth of customization
necessary to support modern research pipelines. Modern computa-
tional, research effort is dominated by big data sets. Working
with these data sets puts pressure on network, compute, and stor-
age resources. Identifying and eliminating resource constraints
is crucial to facilitating science at this scale. Network, compute,
and storage resource constraints are often solvable with simple
upgrades to hardware that increases capacity. This paper detailed
improvements to network and compute resources at the campus
which directly stemmed from the effort to process the HCP900 data
set. The improvements will help support processing of terabyte
scale data sets. Additional improvements are planned by connect-
ing the cluster file system to high bandwidth Science DMZ DTNs

Figure 5.1: Detection of NVIDIA GPUs via CUDA environ-
ment
and expanding availability of GPU-enabled applications to prepare for future large scale data sets.

Software enhancements to support different platform features tend to have greater expenses and are not always immediately apparent. The more a local environment diverges from the environment from the group that develops the tools, the greater likelihood local site maintainers will need to adapt and migrate those tools to work efficiently on local platforms. Without a project framework to integrate multi-platform support from the local site with the upstream code base, these modifications will be left to individual discovery of each site using the tools. Depending on the level of maturity in delivering systems that support specific domain science, the understanding of tools, and the availability of labor, these problems may or may not be solvable at specific sites. In order for these enhancements to reach the widest audience, such enhancements should be developed openly to ensure the maximum reach of community contributions to those without the means to solve them.
