Summary: Phenolic compounds such as chlorogenic acid, cryptochlorogenic acid, neochlorogenic acid and caffeic acid are widely distributed in fruits, vegetables and traditional Chinese medicines with a wide range of biological activities. Tyrosinase plays a critical role in the food industry, but recent studies have proposed unexplored aspects of clinical application. Tyrosinase-catalyzed oxidation of four polyphenols as well as its underlying mechanism remains unclear. In the current work, we investigated the kinetic properties of tyrosinase-catalyzed oxidation of the four polyphenols of interest. To measure the unstable o-quinone products, an analytical method using 3-methyl-2-benzothiazolinone hydrazone (MBTH) was established. The optimal incubation time, buffer pH, temperature and enzyme concentration for the enzyme activity in the presence of each polyphenol of interest were investigated. Under the final optimized conditions, the kinetics and substrate specificity of four polyphenols were examined. Kinetic data showed that tyrosinase had the greatest substrate affinity to chlorogenic acid compared with its isomers and caffeic acid. The catalytic efficiency with chlorogenic acid was 8- to 15-fold higher than that with the other 3 polyphenols. Molecular docking study demonstrated that the tight binding of chlorogenic acid at the peripheral site should be the major reason for the specificity to chlorogenic acid. In light of this, the rational design of high-affinity inhibitors against tyrosinase may focus on the binding of both the Cu site and peripheral site. This study will supply a basis for the selection of phenolic acids in food industry and health care.

Key words: polyphenols; tyrosinase; kinetic characterization; molecular docking

Daily diet plays an important role in disease prevention. Evidence shows that people can benefit from plant phenolic compounds which are often absorbed from the diet[1]. Phenolic compounds are ubiquitous in plants and consist of a large number of secondary metabolites derived from pentose phosphate, shikimate and phenylpropanoid pathways[2]. The composition and amount of phenolic substances are determined by a variety of genetic and environmental factors[3]. Phenolics not only contribute to the color and sensory characteristics of vegetables and fruits, but also provide protection against pathogens and predators. More importantly, phenolic chemicals are a major source of the intake of natural antioxidants in the human diet[4].

Typical plant-derived phenolic compounds occurring in the human diet include flavonoids, phenolic acids, tannins, stilbens and lignans, etc. It is worthy to note that major classes of phenolic acids are hydroxycinnamic acids and hydroxybenzoic acids. The main polyphenolic representatives of hydroxycinnamic acids are chlorogenic acid and caffeic acid[5]. The latter is found in foods largely as an ester form with quinic acid called chlorogenic acid[6]. Chlorogenic acid, also known as 3-O-caffeoyl quinine, is widely distributed in fruits (apple), vegetables (potato), drinks such as tea, coffee[7], wine[8], traditional Chinese medicines such as honeysuckle[9], gardenia[10] and even tobacco[11]. According to different esterification sites of quinine, 4-O-caffeoyl quinine (cryptochlorogenic
Tyrosinase is a copper-containing monooxygenase, widely distributed in plants, micro-organisms and mammals. Tyrosinase catalyzes two types of reaction, by which monophenols and o-diphenols are oxidized to o-quinones, respectively. The role of tyrosinase for triggering enzymatic browning reactions has been well established in the food industry. Searching potent tyrosinase inhibitors is of great importance for postponing the discoloration process. To gain this goal, a large number of chemicals from both natural and synthetic sources have been tried. However, more efforts are still required to identify better inhibitors without obvious adverse side effect. Recently, a variety of studies have proposed several previously unexplored aspects of tyrosinase in clinical studies. Tyrosinase also plays a key role in the pigments synthesis such as melanin, which regulates the color of hair and skin. Tyrosinase is considered as a target in the treatment of specific dermatological diseases associated with melanin hyperpigmentation. Tyrosinase is also known as an autoantigen in various autoimmune disease and serves as a marker for vitiligo. Despite contradictory opinion concerning the role of tyrosinase in mutagenicity and tumor suppression, melanocyte-directed tyrosinase prodrug therapy might offer a highly selective drug delivery approach for malignant melanoma.

Chlorogenic acid has been reported as a substrate of polyphenol oxidase derived from apple and dill. Chlorogenic acid, 5-O-caffeoyl quinic acid (neochlorogenic acid) are two important isomers of chlorogenic acid. Recently, an increasing number of research papers have been published to ascertain the nutritional benefits and physiological effect. Scientific evidence shows that chlorogenic acid has a wide range of biological activities, such as antioxidant and anti-mutagenesis, cardiovascular protection, antibacteria and antivirus, immune regulation, lowering blood glucose and blood lipids. Moreover, pharmacological studies have also demonstrated that both cryptochlorogenic acid and neochlorogenic acid exhibit excellent antioxidant, antibacterial, antiviral and antipyretic activities. In addition, caffeic acid has also demonstrated antioxidant activity in the prevention of premature aging and antimicrobial activity in the treatment of dermal diseases.

and 60°C, respectively. The mixture of substrate, MBTH and analysis buffer was pre-incubated for 10 min at appropriate temperature and then the reaction was initiated by adding the enzyme. For enzyme optimization, final concentrations of 5–500 U/mL, 10–1000 U/mL and 10–1500 U/mL tyrosinase were used for chlorogenic acid, neochlorogenic acid and other two substrates, respectively. The optimal incubation time, incubation buffer pH, temperature and enzyme concentration obtained for tyrosinase-catalyzed oxidation were applied for the following kinetic study.

1.2.3 Kinetics of Tyrosinase-mediated Oxidation of Polyphenols

The kinetics and substrates specificity of four polyphenols were examined under the final optimized incubation conditions. The reaction mixture consisting of 24 mmol/L MBTH, enzyme solution, 100 mmol/L phosphate buffer at a final volume of 150 µL was pre-incubated for 10 min. The reaction was initiated by the addition of 50 µL substrate solution and terminated by the addition of 200 µL ice-cold acetonitrile. The kinetics was determined in concentration ranges of 0.025 to 5 mmol/L and 0.1 to 10 mmol/L for chlorogenic acid and other three substrates, respectively. GraphPad prism (version 7.0) was used for the non-linear regression analysis of the kinetic data to calculate the Michaelis-Menten constant (K_m) and the apparent maximum rate (V_max). The catalytic constant (k_cat) was calculated by dividing the apparent maximum rate by total amount of tyrosinase in units of inverse time.

1.2.4 Molecular Docking

All molecular docking simulations were carried out using AutoDock Vina[35]. The tyrosinase structure was taken from our previous study[34] which was constructed from crystal structure 2Y9W[35] and optimized by quantum mechanics/molecular mechanics (QM/MM) calculations. The four polyphenols, i.e., chlorogenic acid, neochlorogenic acid, cryptochlorogenic acid, and caffeic acid, were built up by using OpenBabel program[36]. Both the receptor and ligands were prepared by using AutoDock Tools[37]. The search space was restricted to a box of 20 × 20 × 20 Å (center = 5, 25, 103). This is sufficient to cover the binding pocket. Default values were used for all parameters. After docking, the top binding poses were selected for binding mode analysis.

2 RESULTS AND DISCUSSION

2.1 Analytical Assay Development for the Reaction Products

The product resulting from the enzymatic oxidation of chlorogenic acid, the o-quinone, has been reported to be unstable substance[38]. In this situation, reliable analytical method becomes a prerequisite for such studies. Kanako et al detected the decrease in substrate concentration using a spectrophotometric method[39]. The analytical assay that focuses on the appearance of a stable chromatophoric compound demonstrates obvious advantages over methods that quantify substrate disappearance. Halis et al and Karla et al measured the o-quinones formation directly by the increased absorbance at maximum wavelength[31, 40]. As is known, such unstable o-quinone suffers the attack of potent nucleophilic reagents and generates chromatophoric adducts with clear stoichiometry. Spectrophotometric methods for measuring the activity of tyrosinase have been summarized and discussed in previously published review[41]. Among the commonly used nucleophilic reagents, MBTH and L-proline were used to characterize both monophenolase and diphenolase activity by measuring the accumulation of chromatophoric substance. In addition, Muñoz et al employed ascorbic acid as reducing agent to measure its disappearance as a result of oxidation by the quinones[38].

As expected, we found the instability of o-quinones which quickly polymerized to colorful pigments. In this situation, the accurate enzyme activity results depended upon the reliability of analytical approaches. Compared with other analytical methods, the MBTH assay showed obvious advantages that MBTH conjugates of o-quinones were more stable than other conjugation forms. The MBTH assay provided a feasible way to detect the oxidation products by avoiding their losses caused by pigments production. In addition, the MBTH method was also proved to be more convenient and economical.

In the current study, we established a sensitive and effective method using MBTH[32] to trap the o-quinone formed in the tyrosinase-catalyzed oxidation. As shown in fig. 1, the maximum absorbance wavelength of the reaction products of chlorogenic acid,
cryptochlorogenic acid, neochlorogenic acid and caffeic acid was 521, 526, 530, 516 nm, respectively. The four polyphenols reacted with excessive enzymes under the final optimized conditions. The calibration curves were found to be linear in corresponding concentration ranges of 0–100 μmol/L and 0–250 μmol/L for neochlorogenic acid and other three substrates, respectively (fig. 2). The typical slope, intercept and correlation coefficient of calibration curves varied among substrates of interest (fig. 2). As expected, when the substrates concentration reached a certain higher level above the upper limit of quantification of the calibration curve, the absorbance tends to be saturated.

### 2.2 Condition Optimization for Tyrosinase Activity

We investigated the effect of incubation time, incubation buffer pH, temperature and enzyme concentration on tyrosinase-catalyzed oxidation of four polyphenols. To ensure that kinetic study was performed under linear conditions, the effect of incubation time on the product amount directly measured by the absorbance was studied over different time range for specific substrate. As shown in fig. 3, the absorbance increased linearly with the incubation time of 10, 15, 30 and 80 min for caffeic acid, chlorogenic acid, neochlorogenic acid and cryptochlorogenic acid.

---

**Fig. 2** The calibration curve of the four polyphenols reacted with excessive enzymes under the final optimized conditions

**Fig. 3** Incubation time optimization for tyrosinase mediated oxidation of four polyphenols
acid, neochlorogenic acid and cryptochlorogenic acid, respectively. 10-, 15-, 30- and 80-min incubation time was selected for the kinetic studies of the above mentioned compounds, because the oxidation rate was linear up to these time points and adequate amount of oxidation product was generated for spectrophotometric measurement. The difference of optimum time among the four polyphenol substrates may be attributed to the different structure of polyphenols, which may lead to different affinity with enzymes.

Polyphenol oxidase is a protein containing copper ions. Inappropriate pH can affect the activity of polyphenol oxidase through denaturation of copper ions and proteins. As shown in fig. 4, the pH of the incubation buffer seems to have an obvious influence on the reaction rate. For chlorogenic acid, enzyme activity was decreased in incubation buffer with increased pH, while enzyme activity was increased when pH was greater than 6.5 for cryptochlorogenic acid. Unlike chlorogenic acid and cryptochlorogenic acid, peak enzyme activity was observed at pH 5.5 and 6.0 for neochlorogenic acid and caffeic acid respectively. Different optimum pHs for polyphenol oxidase derived from various sources have been reported in previously published literature\(^{[31, 42–45]}\). For example, optimum pH with chlorogenic acid substrate was found to be phosphate buffer pH 5.5 for polyphenol oxidase obtained from dill (\textit{Anethum graveolens})\(^{[31]}\). The inconsistency between previous and our findings might be due to the source and the purity of the enzyme as well as difference in ionic strength of the incubation buffer\(^{[31, 42]}\). Taken together, the optimum pH of 6.0 was chosen for chlorogenic acid, cryptochlorogenic acid and caffeic acid, while the optimum pH of 5.5 was selected for neochlorogenic acid.

An increasing number of active enzyme molecules was associated with the increase of temperature. However, the denaturation of enzyme would be aggravated with the gradual increase of temperature, leading to the gradual loss of enzyme catalytic activity. Figure 5 shows that with the rise of temperature, the enzyme activity increased gradually when chlorogenic acid, cryptochlorogenic acid and caffeic acid were used as substrates, and reached the maximum activity at 37°C, which may be due to the fact that an increase of temperature to a certain extent causes the enzyme transferring to a catalytic conformation in favor of the substrate. Interestingly, it was found that the optimum temperature was 10°C for chlorogenic acid when dill-derived polyphenol oxidase was used. This might be also explained by the difference in the source and the purity of the enzyme as well as the ionic strength of incubation buffer\(^{[31, 42]}\). The enzyme activity of neochlorogenic acid at 25°C is slightly higher than that at 37°C. As the temperature continues to rise, however, the active conformation of the enzyme might be altered and the enzyme activity declined. When the temperature reached 60°C, at least 5-fold decrease in enzyme activity was observed for all four polyphenols of interest. Therefore, the optimum temperature of 25°C and 37°C was chosen for neochlorogenic acid and other three polyphenols of interest, respectively.

When the enzyme concentration was low, the enzyme activity increased linearly with the enzyme concentration since the substrate was overabundant at low enzyme concentrations (fig. 6). The reaction product generation rate was saturated once the enzyme concentration reached a certain high level (fig. 6). The explanation might be that under high enzyme concentration condition, substrate was not sufficient for

Fig. 4 The pH optimization for tyrosinase mediated oxidation of four polyphenols

Fig. 5 The temperature optimization for tyrosinase mediated oxidation of four polyphenols
enzyme molecule binding and thus substrate-limited saturation was observed. Good linear relationship was achieved between 0–100 U/mL (chlorogenic acid), 0–80 U/mL (cryptochlorogenic acid), 0–100 U/mL (neochlorogenic acid), and 0–100 U/mL (caffeic acid), respectively.

2.3 Kinetic Analysis of Tyrosinase-catalyzed Oxidation of Polyphenols

The kinetics of the four polyphenols was determined over pre-defined concentration range under the final optimal incubation conditions. The rate of product formation with respect to the substrates concentration demonstrated nonlinear Michaelis-Menten kinetics for four polyphenols (fig. 7). The Michaelis-Menten parameters including apparent $K_m$ and $V_{max}$ as well as catalytic constant $k_{cat}$ and $k_{cat}/K_m$ are listed in table 1. As shown in table 1, mushroom tyrosinase has better affinity towards chlorogenic acid ($K_m = 0.06$ mmol/L) than other three substrates, as indicated by the high $V_{max}/K_m$ ratio. Our finding was in good agreement with previously reported $K_m$ of chlorogenic acid using dill-derived polyphenol oxidase[31]. When $V_{max}$ values are compared for the four substrates of interest, it was also found that $V_{max}$ for chlorogenic acid was higher than that for other three substrates. The parameter of catalytic efficiency ($k_{cat}$ and $k_{cat}/K_m$) indicated that the tyrosinase-catalyzed oxidation of chlorogenic acid has the highest catalytic efficiency, which is 8- to 15-fold.

higher than that of the other 3 polyphenols. Except for the caffeic acid, other three compounds are isomers to each other. They are the esters of caffeic acid and quinic acid. The differences of these polyphenol isomers lie only in the esterification sites of quinine (see the first column in fig. 8). However, such structurally similar polyphenols exhibit significantly different kinetic behavior.

2.4 The Binding Modes of Polyphenols in Tyrosinase

It’s of great interest to understand why tyrosinase-catalyzed oxidation is much more specific to chlorogenic acid than to the other polyphenols. Shown in fig. 8 are the chemical structures of polyphenols and binding modes obtained from molecular docking. The

![Fig. 8](image-url) The binding modes of (A) chlorogenic acid, (B) cryptochlorogenic acid, (C) neochlorogenic acid, and (D) caffeic acid in tyrosinase binding pocket obtained from molecular docking. The carbon atoms of protein and ligands were colored with green and yellow, respectively. The copper, oxygen, nitrogen, and hydrogen atoms were colored with brown, red, blue, and white, respectively. The hydrogen bonds were rendered by black dash lines. The distances between phenol oxygen and the closest copper ion were labeled by blue dash lines.
binding pocket consisted of two binding sites, which are labeled as Cu site and peripheral site, respectively. The Cu site contains the two copper ions, and the adjacent peripheral site is formed by residues 81–86 and 321–324. As expected, all 4 polyphenols bind at the Cu site with their caffeic groups, in which the phenol groups point toward the copper ions. This observation is consistent with the fact that it is the phenol groups being oxidized. In addition to Cu site, chlorogenic acid and its isomers occupy the peripheral site with their quinic group (see the second column of fig. 8). The details of quinic group binding at the peripheral site (see the last column of fig. 8) show that chlorogenic acid forms 4 hydrogen bonds with the peripheral site, whereas neochlorogenic acid and cryptochlorogenic acid each forms only 2 hydrogen bonds. Clearly, chlorogenic acid binds tighter than the other two isomers, which explains why chlorogenic acid has the smallest $K_m$ value. As for caffeic acid, its molecular size is much smaller than other three substrates. It is thus not surprising to see that the affinity of caffeic acid is smaller than other three polyphenols, which results in the largest $K_m$ value among all 4 polyphenols. Also, the second-best binding pose of caffeic acid, which is shown in fig. 8D, suggests a larger $K_m$ value. The docking score of the second-best binding pose is only 0.7 kcal/mol higher than that of the best binding mode. The ability to bind also to the peripheral site indicates that part of caffeic acids is unable to participate the oxidation reaction, and thus increases the observed $K_m$ value.

The distance between the phenol oxygen and the closest copper ion ($d_{O-Cu}$) may reflect how fast the oxidation reaction proceeds. The closer the distance is, the more likely the oxidation proceeds faster. As seen from the last column of fig. 8, the $d_{O-Cu}$ for chlorogenic acid is 3.5 Å. It is significantly smaller than those for the other 3 polyphenols, suggesting that it is easier for chlorogenic acid to reach the transition state. Therefore, chlorogenic acid exhibits the largest $k_{cat}$ value. Neochlorogenic acid and cryptochlorogenic acid have larger $d_{O-Cu}$ and smaller $k_{cat}$. This is most likely due to the different binding modes of quinic groups at the peripheral site, which hinders the caffeic groups of neochlorogenic acid and cryptochlorogenic acid to more closely approach the copper ions. Interestingly, the best binding pose of caffeic acid displays a $d_{O-Cu}$ of 4.0 Å that is shorter than that of neochlorogenic acid and cryptochlorogenic acid. However, oxidation of caffeic acid is still the slowest one, suggesting that the substituent effect is very important in the tyrosinase-catalyzed oxidation reaction.

In summary, more specificity of tyrosinase to chlorogenic acid is majorly because of the tighter binding of chlorogenic acid at the peripheral site, which concurrently enables it to more closely approach the copper ions. In light of this, the rational design of high-affinity inhibitors against tyrosinase may focus on the binding of both the Cu site and peripheral site. Natural bioactive components such as phenolic compounds might be good substrates or inhibitors of tyrosinase due to possible interaction between phenolic compounds and the copper ions of tyrosinase. Because tyrosinase plays an important role in melanin synthesis, phenolic compounds such as chlorogenic acid might be widely used in health care and cosmetic products.

3 CONCLUSION

In this study, we established an MBTH assay to trap the o-quinone formed in the tyrosinase-catalyzed oxidation for enzyme kinetic study of the four polyphenols, i.e., chlorogenic acid, cryptochlorogenic acid, neochlorogenic acid, and caffeic acid. This analytical method overcomes the problem that the unstable o-quinone occurring from the enzyme oxidation of polyphenols negatively affected the quantification of the reaction product. The effect of experimental factors such as incubation time, pH, temperature and enzyme concentration were investigated and optimal incubation conditions would be applied for kinetics characterization of the four polyphenols. The optimum incubation time, buffer pH, temperature and enzyme level varied among substrates. Our kinetic data show that tyrosinase has the greatest affinity to chlorogenic acid compared with its isomers and caffeic acid. The catalytic efficiency with chlorogenic acid is 8- to 15-fold higher than that with the other 3 polyphenols. The reason for such a great substrate specificity has been elucidated by our molecular docking results. The tight binding of chlorogenic acid at the peripheral site, which concurrently enables it to more closely approach the copper ions, should be the major reason for the specificity to chlorogenic acid. In light of this, the rational design of high-affinity inhibitors against tyrosinase may focus on the binding of both the Cu site and peripheral site.
