Abstract

We experimentally show the enhancement of the Faraday and transverse magneto-optical Kerr effects in the two-dimensional arrays of nanocylinders made of bismuth-substituted iron-garnet and supporting both localized and lattice modes. Simultaneous excitation of these modes makes it possible to increase the Faraday rotation by 3 times and TMOKE by an order of magnitude compared to the smooth magnetic film of the equal effective thickness. Both magneto-optical effects are enhanced in wide spectral and angular ranges making the nanocylinder array magnetic dielectric structures promising for applications with short and tightly-focused laser pulses.
Introduction

Nowadays, the magneto-optical effects are widely used in different devices such as routers, optical isolators, magneto-optical sensors, modulators and magnetometers. From the point of view of the device miniaturization, it is important to design the nanostructures with efficient magneto-optical interaction providing the enhancement of the magneto-optical effects compared to the same smooth films.

First we focused on the enhancement of the magneto-optical Faraday effect which is the rotation of linear polarization of light passing through a material along an external magnetic field. The value of the rotation angle is directly proportional to the specific Faraday rotation of the material and the path traversed by light in the material. Since there is a dependence on the length of the path, miniaturization of devices inevitably leads to a decrease in the Faraday rotation value. Therefore, it is important to find ways to improve magneto-optical response of the materials. One of the straightforward ways to enhance the magneto-optical Faraday rotation in thin films is utilization of the photonic crystals with microcavity (defect) magnetic layers. Photonic crystals surrounding a magnetic layer act as a Bragg mirrors leading to the multiple re-reflection of light inside the magnetic layer like in the Fabry-Pérot cavity. Faraday polarization rotation constantly increases each loop the light travels inside the magnetic layer. Such amplification of the Faraday effect can be attributed to the increase in the effective path length of light through the material.

At the same time, it is possible to enhance magneto-optical effects via excitation of the optical resonances in the magnetic nanostructures, which can be attributed to the increase in the interaction time between light and a magnetic medium. Various types of nanostructures were shown to increase the magneto-optical effects. For example magneto-plasmonic crystals offer an opportunity to increase the Faraday and Kerr effects due to excitation of surface plasmon polaritons. The enhancement could be observed due to the excitation of plasmonic resonances in metallic particles or nanoantennas, plasmonic nanocavities and in the artificial metal-dielectric composites with hyperbolic dispersion. The possibility of the
magneto-optical effects enhancement was also reported for structures that maintain simultaneously several kinds of optical modes. However, metals in such structures cause high absorption losses, broadening of observed resonances and decrease of the base (transmitted) signal. This problem can be solved by using all-dielectric resonant nanostructures. Recent studies show that besides the amplification of the Faraday rotation, one may obtain high magneto-optical intensity modulation in the transverse configuration of the external magnetic field applied to the structure. However, such amplification is observed in a very small angular and wavelength range due to the high Q-factor of the guided wave resonances.

Here we show the enhancement of the Faraday and transverse magneto-optical Kerr effect (TMOKE) in the two-dimensional arrays of cylinders made of bismuth-substituted iron-garnet that support both localized (Fabry–Pérot-like) and lattice (guided-like) modes. Simultaneous excitation of these modes makes it possible to increase the Faraday rotation by 3 times compared to the smooth magnetic film of the equal effective thickness. The one order increase of TMOKE is also observed in the structure in a wide angular range.

**Optical modes of the iron-garnet nanocylinder 2D array**

The samples under research are two-dimensional arrays of cylinders etched in a bismuth-substituted iron garnet (BIG) thin film (the thickness is 515 nm) of Bi$_{1.0}$Lu$_{0.5}$Gd$_{1.5}$Fe$_{4.2}$Al$_{0.8}$O$_{12}$/Bi$_{2.8}$Y$_{0.2}$Fe$_{5.0}$O$_{12}$ deposited by magnetron sputtering on a SiO$_2$ substrate (Fig. 1). The nanocylinders were patterned on a 550 nm thick spin-coated positive e-beam resist (ZEP-520A) by electron-beam exposure with a uniform dose of 140 µC/cm² and under proximity effect correction (PEC) using a 100 KeV e-beam lithography system (VISTEC EBPG 5000+). A 30 nm-thick gold layer was also coated on top to avoid electrical charging of the dielectric garnet film during e-beam exposure. After which, the gold layer was first removed by wet etching in a gold etchant solution and then the resist was developed in an amyl acetate solution. The resist patterns were then transferred onto the BIG film by sputter-etching at
a rate of 2.5 nm/minute with argon-ion beam. The temperature of the sample stage was
maintained at 60°C throughout the etching process to avoid hardening of the resist, which
was then removed using resist remover N-methyl-2-pyrrolidine (NMP) by heating at 800°C
for about half an hour. The BIG cylinders with diameter \( d = 500 \text{ nm}, 550 \text{ nm}, 600 \text{ nm},
650 \text{ nm} \) for the studied samples) having the same height \( h = 515 \text{ nm} \) were arranged in a
square lattice with a period of \( P = 900 \text{ nm} \).

\[ \text{Fig. 1. Schematic representation of the BIG nanocylinder 2D array and the excited localized}
\]
\[ \text{and lattice modes.} \]

Such nanostructured material supports two kinds of the optical modes: the localized
and lattice modes. The former could be understood in a frame of the waveguide theory as
the modes of cylinder waveguides.\(^{50,51}\) The waveguide with a circular cross-section supports
various types of modes: TM and TE modes with axially-symmetric polarizations, and hybrid
EH modes with the mixed polarizations. As in the present experiments the nanocylinders are
illuminated by a rather wide linearly-polarized collimated light beam of \( \sim 300 \mu \text{m} \) diameter
with a uniform distribution of the \( \mathbf{E} \) vector at the scale of the nanocylinder, only modes
with azimuth independent \( \mathbf{E} \)-field distribution could be excited. Actually, among waveguide
modes only EH\(_{1,m} \) modes (which correspond to the Linearly Polarized LP\(_{0,m} \) modes which
are given by the characteristic equation
\[ u \left[ J_{m-1}(u)/J_m(u) \right] = -w \left[ K_{m-1}(w)/K_m(w) \right] \]
in the case of weak refractive index contrast\(^{52}\) have zero orbital number and azimuth independent
spatial distribution of polarization vector inside the core. The field of such mode in the BIG
cylinder has the form: \( E_x = J_0(2U_m r/d) e_\mathbf{\nu} \) where \( e_\mathbf{\nu} \) is the unit polarization vector, \( J_0 \) is a Bessel function, \( r = \sqrt{x^2 + y^2} \) is the radial coordinate and \( U_m = \frac{1}{2}k_0 d \sqrt{n^2_{\text{BIG}} - n^2_m} \) is the dimensionless constant that depends on the mode refractive index \( n_m \), \( k_0 \) is the wave vector of the incident light.

Actually, we deal with a piece of the cylinder waveguide with the two facets neighboured by air \((n_a = 1)\) and fused silica \((n_{\text{SiO}_2} = 1.45)\), correspondingly. These facets act as the mirrors forming a 'vertical' Fabry–Pérot cavity (Fig. 1) and causing the minima and maxima in the transmittance spectra (see green arrows in Fig. 2b). The difference of the mode refractive indices \( n_m \) for the modes of different orders leads to the differences in the resonant wavelengths. For example, as the numerical simulations show, the localized mode at \( \lambda \sim 800 \text{ nm} \) is the EH\textsubscript{1,2} mode (Fig. 2d) forming a standing wave (Fig. 2c) inside the BIG cylinder.

Obviously, the Q-factor of such a cavity is rather low, therefore the observed resonances are spectrally rather wide, 50-100 nm in width, approximately. The positions of the observed resonances differ from the interference minima and maxima of the smooth BIG film (Fig. 2b), and are independent on the angle of incidence. These localized resonance spectral positions strongly depend on the diameter of the nanocylinder and experience a redshift if diameter increases.

Figure 2(a) shows that the angle-dependent lattice modes are also excited in the structure. These modes are formed due to the interaction of the leaking near-field radiation of the localized modes in the cylinders arranged periodically. Such modes can be treated as the guided modes propagating in the lateral direction in an effective planar waveguide with core formed by the nanopatterned BIG film. In a sense, these modes are similar to the lattice surface plasmons. In the 2D lattice, such guided modes can be excited under the following phase-matching condition:

\[
k_r + G_x l_x + G_y l_y = \beta
\]

(1)

where \( k_r = k_0 \sin \theta e_\mathbf{\nu} \) is the tangential component of the incident light wavevector, \( \theta \) is the angle of incidence, \( l_x \) and \( l_y \) are integers which correspond to the order of the lattice mode,
Fig. 2. (a) False-color plot for the experimental dependence of the transmittance on the light incidence angle and wavelength for the structure with $d = 650$ nm; (b) Experimental transmittance spectra of the smooth film (black) and the array of cylinders (red) with $d = 650$ nm (the green (yellow) arrows indicate the dips corresponding to the excitation of the (lattice modes) eigenmodes). (c), (d) False-color plots for the spatial distributions of light electric field value $|E|$ at the excitation of the localized mode at $\lambda = 800$ nm in (c) $x - z$ and (d) $x - y$ planes.
$G_x = G_y = \frac{2\pi}{P}$ are the absolute values of the reciprocal lattice vectors, $P$ is the period of structure, $\lambda$ is the wavelength of the incidence light, $\beta$ is the wave vector of the lattice mode. As the period of the gratings is rather high ($P > \lambda$, $P > n_{SiO_2}\lambda$) and there are several propagating diffraction orders generated in reflection and transmission, the efficiency of the lattice mode excitation is not very high. In Fig. 2a these modes reveal themselves intersecting the angle-independent resonances of the localized modes. In Fig. 2b lattice modes can be located as bents in the transmittance curve and are pointed with yellow arrows.

As it will be shown below, both of these modes are involved in the magneto-optical interaction of light with the 2D nanocylinder array. We will focus on the analysis of the localized mode $EH_{1,2}$ excited at $\lambda \sim 800$ nm as it exists in all of the fabricated structures that makes it possible to track the evolution of the magneto-optical response with the variation of the nanocylinder diameter and appearance of the lattice modes in its vicinity.

**The Faraday effect with localized and lattice modes**

The magnetic film produces the magneto-optical Faraday rotation of the polarization of the transmitted light under the application of the external magnetic field parallel to the light wavevector. Such magnetization also influences the characteristics of the lattice and localized modes, in the different ways.

The localized modes of the nanocylinders have polarization degeneracy in the non-magnetic case, i.e. the two $EH_{1,m}$ modes of the same order $m$ and orthogonal polarizations $e_x$ and $e_y$ have the same refractive index $n_{1,m}$. Actually, modes with circular polarization unit vectors $e_x + i e_y$ and $e_x - i e_y$ are the eigen modes of the system with the same refractive index $n_{1,m}$. Similar to the case of a smooth film, application of the external magnetic field along the cylindrical waveguide axes lifts this degeneracy so that the refractive indices of the both modes acquire additional magneto-optical terms of different signs. This birefrigence between the two circularly polarized modes excited by the linearly-polarized incident light
results in the Faraday rotation of its polarization. Notice that due to the complex dispersion of the nanocylinder modes such magneto-optical circular birefringence differs from the one in a smooth film.

The lattice modes are also sensitive to the magnetization, however, the situation is more complicated. Actually, these modes have linear eigen polarization in the non-magnetic structure (for example, the TM-mode with $\{E_x, E_z, H_y\}$). External magnetic field applied normally to the structure changes these exact analytical solutions of Maxwell’s equations and gives the different polarization of the eigen modes. The eigenmode still has the same ($\{E_x, E_z, H_y\}$ for TM, for example) components but acquires linear in magnetization orthogonal (TE in the considered case $\{E_y, H_x, H_z\}$) components. The additional components are not associated with some other mode of the orthogonal polarization existing in the structure and appear just as a rigorous solution of Maxwell’s equations for the corresponding constitutive equations.

It is important that the presence of the interface of the materials and the corresponding boundary conditions for the electromagnetic field also impose restrictions on the Faraday-like rotation of the polarization during the propagation along the surface. Thus quasi-TM and quasi-TE modes appear in the magnetized medium. The refractive indices of the quasi-TM and quasi-TE modes remain the same as for the non-magnetic case. However, for rather thick magnetic films the dispersions of the quasi-TM and quasi-TE modes are very close to each other so that appearance of the magneto-optically induced orthogonal polarization components results in the energy swap between the quasi-TM and quasi-TE resulting in the polarization rotation. This mechanism is less efficient as they the lattice modes in are rather shallow due to the high scattering during the propagation in lateral direction. Nevertheless, both types of the modes and both mechanisms are involved in the Faraday rotation observed in the structure as discussed below.

In order to compare the Faraday rotations in both cases correctly, we have to take into account the fact that the 2D arrays with different diameters of the nanocylinders have
different specific amount of the magnetic BIG material per period. This amount is also
different from the one in the smooth film of the same physical thickness. On the other
hand, the specific Faraday rotation itself depends on the wavelength of the light thus it will
inevitably differ for the resonances excited at different wavelengths. Therefore, to compare
the nanostructure-induced enhancement of the Faraday rotation angles obtained in various
structures more correctly, we calculate the value of relative enhancement as:

\[ \phi(\lambda) = \frac{4\pi^2}{\pi d^2} \frac{\Phi_{\text{arr}}(\lambda)}{\Phi_{\text{film}}(\lambda)} \]  

where \( \Phi_{\text{arr}} \) is the Faraday rotation angle measured in 2D array of cylinders, \( \Phi_{\text{film}} \) is the Fara-
day rotation angle measured in the smooth BIG film of the same thickness and composition,
and the factor \( \frac{4\pi^2}{\pi d^2} \) accounts for the variation of the relative amount of BIG material.

![Fig. 3. Relative enhancement of (a) transmittance and (b) the Faraday rotation in the
nanocylinder arrays with different nanocylinder diameters (see the legends). In (b) the
spectral range in the vicinity of EH\(_{1,2}\) localized resonance is highlighted.](image)

Figure 3(a) shows that for structures with diameters of cylinders \( d = 500 \text{ nm} \) and \( d = 550 \text{ nm} \) at the wavelengths in the vicinity of 700 nm, only the localized eigenmode of cylinders
is excited. The relative enhancement of the Faraday effect in these structures is less than 2
times in comparison with a smooth BIG film. For structure with $d = 600$ nm in the vicinity of the localized eigenmode excitation ($\lambda = 770$ nm) the lattice mode is also excited so that the $\phi$ spectra acquire the Fano shape due to the superposition of these two resonances. Simultaneous excitation of the same eigenmode and two lattice modes in the structure with $d = 650$ nm results in the interaction of the three magneto-optical resonances. This leads to the further change of the resonance shape which is more significant and makes the relative enhancement value larger up to 3.75 times in comparison with that of a smooth iron garnet film.

Therefore, the simultaneous excitation of the localized and lattice modes is shown to be responsible for nearly 4-times relative enhancement in Faraday rotation with respect to a smooth film of the same thickness.

Transverse magneto-optical Kerr effect with localized and lattice modes

The transverse magnetic field applied to the structure causes the magneto-optical Kerr effect that results into the modulation of the transmitted or reflected light intensity. This effect is below $10^{-4}$ in magnitude for the smooth iron-garnet films, however, it can be enhanced by the mode excitation.

The mechanism of the TMOKE amplification under the excitation of the lattice modes is the non-reciprocal magneto-optical variation of the mode propagation constant $\beta = \beta(H = 0) + \Delta\beta(H)$ that changes the resonance conditions according to Eq. (1) and causes a variation of the intensity of the transmitted and reflected light. The detailed description of this mechanism for all-dielectric gratings was presented elsewhere.\textsuperscript{47} Although it allows one to observe a strong enhancement of TMOKE, this enhancement is provided in a very narrow angular and frequency range in the vicinity of the lattice mode resonances. This limitation could be overcome if localized modes with angular-independent and wide resonances are
excited simultaneously with the lattice ones.

![Fig. 4. TMOKE in transmission for nanocylinder array with $d = 650$ nm. (a) False-color plot of the dependence of TMOKE of the light with the incident angle and the wavelength. (b) Angular dependence of TMOKE and transmittance at the wavelength $\lambda = 630$ nm.](image)

Figure 4 shows the TMOKE spectra for the nanocylinder array with $d = 650$ nm. One may see that the TMOKE is enhanced in the whole measurement range and the resonances are broad and have large angular width. The most interesting is the TMOKE enhancement up to 5% for $\lambda = 630$ nm, and exceeds 2% for the angles of incidence from 5 to 35 deg. It opens up new possibilities for the device miniaturization since such wide spectra allows one for the utilization of tightly-focused light for the efficient magneto-optical modulation.

**Conclusion**

The enhancement of the Faraday and transverse magneto-optical Kerr effects in the two-dimensional arrays of nano-cylinders made of bismuth-substituted iron-garnet were shown experimentally. The feature of the considered structure is the co-existence of both localized (Fabry–Pérot-like) and lattice (guided-like) modes. Simultaneous excitation of these modes makes it possible to increase the Faraday rotation by 3 times compared to that in the
smooth magnetic film of the equal effective thickness. The one order of magnitude increase in TMOKE is also observed in the structure. It is important that both the Faraday rotation and TMOKE are enhanced in wide spectral and angular ranges. This makes the considered structure prospective for magneto-optical applications with tightly-focused femtosecond laser pulses that usually have rather broad frequency and angular spectra.

**Funding**

The study of the Faraday effect was financially supported by the Ministry of Science and Higher Education of the Russian Federation, Megagrant project No. 075-15-2019-1934, and the study of transverse magneto-optical Kerr effect was financially supported by RSF 21-72-10020.
